4. An electrical potential is placed across the gel. The electrical field and time of electrophoresis are chosen, based on the following:
 - (a) The most rapidly migrating particle should not migrate out of the gel.
 - (b) The separation between particles should be sufficient so that each particle forms a separate band.
 - (c) Bacteriophage particles should not disrupt during electrophoresis.
 - (d) The time of electrophoresis should be short enough so that band broadening is not a problem.
 - (e) The electrical current should be low enough so that rise in temperature does not destabilize bacteriophage particles.

The bacteriophage particles are visualized by either light scattering or staining, after electrophoresis (illustrated in the after column of **Figure 3**). Ethidium is a stain used for DNA; Coomassie blue is a stain used for protein. Preparative fractionation should use light

scattering, to avoid stain-induced changing of the bacteriophage particles.

Large scale fractionation of bacteriophage particles is almost never done by gel electrophoresis. Gel electrophoresis is used primarily for analysis, not purification. The reasons are the following:

1. Like rate zonal centrifugation, nondenaturing gel electrophoresis begins with the sample in a small volume. The sample is diluted during fractionation.
2. Recovery of particles after gel electrophoresis is not as good as recovery after fractionation in solution.
3. The bacteriophage particles are contaminated with both agarose and contaminants of agarose, after fractionation.
4. The bacteriophage particles are exposed to products of the electrolysis of water. The result is an unnecessary source of possible damage of bacteriophage particles.

Concluding Remarks

The purification of bacteriophages by centrifugation is a routine procedure. The most difficult requirement is the obtaining of centrifuges. Challenges are encountered primarily when a bacteriophage is unstable during exposure to the conventional conditions of centrifugation. A further challenge is encountered when bacteriophage particles are purified for the purpose of high resolution analysis of structure. This latter challenge is heterogeneity of bacteriophage particles that appear homogeneous when fractionated by centrifugation. Nondenaturing gel electrophoresis can reveal heterogeneity. However, nondenaturing gel electrophoresis has not been useful for preparative fractionation. Thus, a challenge for the future is the development of preparative procedures of nondenaturing gel electrophoresis. This last challenge would be met by development of a procedure of continuous-flow gel electrophoresis. Continuous-flow preparative gel electrophoresis is possible, in theory. Hopefully, it will be achieved in practice.

Introduction

According to the Brønsted–Lowry definition (1923) a base is a proton acceptor:

The stronger the base, the larger is its K_b and consequently the smaller is its pK_b and the larger is the pK_a of the conjugated acid.

There are various types of bases, including natural and synthetic compounds, and they occur in a vast array of products, extending from the alkaloids, sulfa drugs (sulfonamides), dyes (azines, indoles), herbicides (simazine, atrazine, promazine), biogenic amines to numerous other groups.

This chapter includes only aliphatic and aromatic amines and their derivatives, heterocyclic bases and miscellaneous compounds (nitrosamines, amides, hydrazines). Thin-layer chromatography is used extensively for the analysis of bases and can achieve separations of complex mixtures comparable to column liquid chromatography.

Aliphatic Amines

The first attempts to separate aliphatic amines were performed on silica gel using chloroform–ammonia (39 : 1), chloroform–methanol–17% ammonia (2 : 2 : 1), butanol–acetic acid–water (4 : 1 : 5) and phenol–water (8 : 3) as eluents. However, highly volatile amines cannot be chromatographed with an ammoniacal solvent. A systematic collection of data on the chromatographic behaviour of a large number of aliphatic amine hydrochlorides, with particular emphasis on eluents, adsorbents and detection reagents, was published by Prandi (see hR_F values in Table 1, columns 1, 2 and 3).

Silica gel is particularly useful for the adsorption chromatography of amines that have different polarities but does not resolve the fatty amine series. In particular, the R_F values increase as the aliphatic chain length increases but this increase becomes smaller with increasing chain length.

Reversed-phase partition chromatography on paraffin oil–saturated silica gel is useful for the separation of fatty amines. $R_M[\log(1/R_F)^{-1}]$ values for such amines increase as the length of the aliphatic chain increases and there is a linear relationship between R_M and the number of carbon atoms in the molecule.

^aEluents: A and B = chloroform–methanol–17% ammonia in the 82.5 : 15.5 : 2 (A) and 70 : 26 : 4 (B) ratios; C = acetone–17% ammonia (70 : 30 v/v); D = *n*-butanol–acetic acid–water (35 : 5 : 10); E = 1 M acetic acid + 1 M HCl in 30% methanol; F = 2 M NH_4NO_3 .

^bSilica gel G (Merck); detection reagents: 1% ninhydrin solution in ethanol–acetic acid (95 : 5); 1% potassium permanganate + 1% potassium persulfate (1 : 1); 25% iodine methanolic solution; 5% sodium nitroprusside in acetaldehyde–2% sodium carbonate (1 : 1 v/v) solution. Sample volume; 10 μL of a 0.5% water–alcohol solution of the amine hydrochloride.

^cParaffin oil–saturated Kieselguhr G (Merck) layers were prepared by immersing the plates in a 5% solution of the oil in acetone.

^dHome-made plates were prepared by spreading a slurry of 50 g of silica gel G (BDH) in 2% *o*-chlorophenol solution (100 mL). The plates were dried for 24 h at 60°C before use. Detection agent: 3 g ammonium thiocyanate and 1 g cobalt chloride in 20 mL of distilled water (blue spots).

^eThe Sil C₁₈-50 impregnated layers (Macherey-Nagel) were prepared by immersing the plates in a 4% dodecylbenzenesulfonic acid (HDBS) solution in 95% ethanol.

^fHome-made plates were prepared by spreading a slurry of 4 g ammonium tungstophosphate (AWP) and 2 g calcium sulfate hemihydrate in 50 mL of distilled water after stirring 10 min with a magnetic stirrer. Detection agent: 1% ninhydrin solution in a 5 : 1 (v/v) mixture of pyridine and glacial acetic acid.

Sources: Adapted from Prandi C (1978) Thin-layer chromatography of aliphatic amines. *Journal of Chromatography* 155: 149–157; Srivastava SP, Dua VK and Chauhan LS (1980) Chromatographic behaviour of aliphatic amines on phenol-impregnated thin layers. *Journal of Chromatography* 196: 225–235; Lepri L, Desideri PG, Heinler D and Giannessi S (1982) High-performance thin-layer chromatography of nitrogen compounds on layers of RP-18 and Sil C₁₈-50 untreated or impregnated with dodecylbenzenesulfonic acid and of ammonium tungstophosphate. *Journal of Chromatography* 245: 297–308.

Cellulose and aluminium oxide have also been used as adsorbents. The phenomenon of multiple-spot formation of amines on cellulose thin layers when using neutral or weakly acidic eluents is caused by the presence of carboxyl groups in the cellulose. Partial hydrolysis of the amine hydrochloride, volatilization of the liberated hydrochloric acid and the presence of charged groups in silica gel and alumina layers have also resulted in double-spot formation for specific compounds.

Phosphate and acetate-buffered silica gel and impregnated plates have been used. Hydrogen bond formation between the impregnated plates and aliphatic amines influences their chromatographic behaviour on metal salt-impregnated plates and on phenol-impregnated silica-gel layers.

The hR_f values of some amines, obtained on silica gel impregnated with a 2% solution of *o*-chlorophenol using a butanol–acetic acid–water (35 : 5 : 10) mixture as eluent are reported in Table 1 (column 4). No correlation exists between the $\text{p}K_a$ value of the conjugated acid of an amine and its R_M value; it therefore seems that the chromatographic behaviour of such compounds is due to hydrogen bond formation between the amine and silica gel as well as *o*-chlorophenol.

Reversed-phase thin-layer chromatography of several aliphatic mono- and polyamines has been performed on layers of silanized silica gel untreated and

impregnated with anionic and cationic surfactants. Ion-exchange and/or partition contribute to the retention of the amines depending on the type of stationary phase, the percentage of surfactant and the apparent pH of the eluent.

Table 1 (column 5) shows the retention data obtained on Sil C₁₈-50 plates impregnated with a 4% dodecylbenzenesulphonic acid solution in 95% ethanol and eluted with 1 M acetic acid + 1 M hydrochloric acid in 30% methanol. On these plates the retention of polyamines is governed chiefly by an ion-exchange mechanism while aliphatic monoamines can be differentiated according to the number of carbon atoms in their side chain.

Aliphatic amines have been studied on layers of weak and strong ion exchangers, Dowex 50-X4 (Na^+ and H^+), sodium carboxymethylcellulose and Rexyn 102 (Na^+), using hydrochloric acid and various buffer and salt solutions as eluents.

The use of ammonium tungstophosphate (AWP) as a layer material is particularly promising since on this exchanger different affinity sequences in comparison with the above-mentioned results are found (see Table 1, column 6). The behaviour of polyamines is of interest since it seems to be correlated to the distance between the protonated amino groups involved in the ion-exchange process and, in the case of 1,2-diaminoethane and 1,2-diaminopropane, to the steric hindrance of the methyl group.

Quantitative analysis of the diamine hydrochloride recovered from acid-hydrolysed copolyamides prepared from diamine-diacid has been carried out on silica gel G eluting with phenol-*n*-butanol-formic acid-water (5:2:1:2 v/v) or phenol-formic acid-water (74:1:25 v/v). Densitometric scanning was performed using a Shimadzu spectrophotometer at 560 nm after spraying the plates with a 0.2% solution of ninhydrin in ethanol and heating at 90°C for 15 min.

Specific procedures have been developed for alkanolamines. The high performance TLC (HPTLC) behaviour of closely related diethanolamines was studied on silica-gel layers eluted with binary solvents (methanol-chloroform, methanol-dichloromethane, methanol-acetone, acetone-chloroform) and on four types of reversed-phase, chemically bonded, silica gel with methanol-water as mobile phase. Alkanolamines, in particular ethanolamines and iso-propanolamines, are used extensively in hydraulic brake fluids and cutting oils as corrosion inhibitors; the derivatives with fatty acids are used as emulsifiers and detergents. Their separation and identification is performed on neutral silica gel using methylene chloride-95%-ethanol-ammonia (0.880) in the proportions 43:43:15 v/v as eluent. A solution of 0.2% ninhydrin, then alizarin in acetone, is employed to locate the separated alkanolamines. The method has been applied to commercial formulations.

Phenylalkylamines

The structures of alkylamines with an aromatic ring in the side chain are shown in **Figure 1**. The phenylethylamine group comprises a range of natural and synthetic compounds, some of which are used in drug formulations, and includes catecholamines and other biogenic amines which are excreted in the urine. The separation of these compounds by TLC and overpressured-layer chromatography (OPLC) is very important as shown by the numerous studies dealing with the determination of phenylethylamines in pharmaceutical preparations, with their identification as drugs of abuse and with the determination of catecholamines, their metabolites and their precursors in urine. These studies are carried out on silica gel, cellulose thin layers or using reversed-phase chromatography on different ready-for-use plates of silanized silica gel untreated and impregnated with anionic and cationic detergents.

The chromatographic behaviour of these compounds has also been studied on strong and weak ion-exchangers and on layers of AWP, an inorganic synthetic ion exchanger which has been used in the separation of other nitrogen compounds.

Table 2 (column 1) lists the hR_F values of 19 phenylethylamines on reversed-phase OPTI-UPC₁₂ plates eluted with 1 M HCl + 3% KCl in water. The presence of potassium chloride in the eluent accounts for the compactness of the spots. Among the diastereoisomers, the differences in the retention allow the separation of norephedrine from norpseudoephedrine.

The Sil C₁₈-50 plates impregnated with 4% N-DPC and eluted with 0.5 M Na₂CO₃ in 30% methanol (**Table 2**, column 2) show considerable differences in the affinity sequence of phenylethylamines with respect to the untreated layers and an improvement in the separation of both the two diastereoisomers of norephedrine and the two isomers of phenylethylamine.

On layers of RP-18 + 4% dodecylbenzenesulfonic acid (HDBS) (**Table 2**, column 3), the retention of the compounds depends on the concentration of hydrochloric acid in the eluent and can be ascribed to the cation-exchange process between the protonated amino group and the surfactant adsorbed on the layer.

A peculiar behaviour is observed on AWP + CaSO₄· $\frac{1}{2}$ H₂O plates (**Table 2**, column 4) since the steric hindrance of the phenyl group on the carbon atom bound to the amino group allows a complete separation ($\alpha = 1.86$) between the two isomeric phenylethylamines.

The use of *o*-benzenesulfonamido-*p*-benzoquinone in methanol or acetone has been described as a means to detect and distinguish the 3,4-methylenedioxyamphetamine of the 'Ecstasy' group on silica gel 60 F₂₅₄ plates with ethyl acetate-acetone-methanol-25% ammonia (20 + 20 + 8 + 2) solution as eluent.

Derivatized Amines

Direct chromatography on thin layers of primary and secondary amines is frequently difficult due to the strong adsorption of the NH₂ or NH groups to the adsorbents employed. Derivatives are often used to overcome these difficulties. A series of reagents has been recommended for the formation of derivatives of primary and secondary amines in order to assist in separating, identifying and determining such compounds on thin layers. The formulae of the most important reagents are shown in **Figure 2**. The chromatographic behaviour of derivatized amines with some common reagents is shown in **Table 3**. Most of these derivatives are intensely coloured (i.e., DADB-, PABS-, DBAB-) or give fluorescent spots (NBD-); in some cases, however, the detection can be considerably improved by exposure of the plates to iodine vapour or by spraying the chromatogram with 0.01 M sulphuric acid (DBAB-amides).

The procedure used for PABS-amides does not allow characterization of the movement of individual compounds by ordinary R_F values, as the chromatography is continued after the solvent front has reached the upper edge of the plate. Therefore, the hR_X values reported in Table 3 (column 2) represent relative

values with respect to the derivative of *n*-butylamine taken as 100.

The dansylated derivatives of ammonia, 1,3-diaminopropane, 1,4-diaminobutane, 1,5-diaminopentane, spermidine, spermine and histamine were separated on silica-gel 60 plates eluted with

Sources: Adapted from Lepri L, Desideri PG and Coas V (1973) Chromatographic and electrophoretic behaviour of primary mono- and diamines on layers of weak and strong ion exchangers. *Journal of Chromatography* 79: 129–137; Lepri L, Desideri PG and Heimler D (1985) High performance thin-layer chromatography of phenylethylamines and phenolic acids on silanized silica and on ammonium tungstophosphate. *Journal of Chromatography* 347: 303–309.

chloroform–triethylamine (5 : 1 v/v). Putrescine, cadaverine, spermidine and spermine can be quantitatively determined in human urine; higher amounts of the last two amines were found in the urines of cancer patients compared to the values of these substances in normal urine. Dansyl amines can be determined by *in situ* fluorescence on silica gel and, sometimes, on polyamide layers. In favourable cases as little as 10^{−12} moles/spot of a DANS-derivative can be visualized on a normal thin-layer plate.

The separation and quantification of dansylated biogenic amines in vegetables have been recently performed on 20 × 20 cm silica-gel HPTLC plates with stepwise gradient elution using the Personal OPLC BS50 overpressured-layer chromatography apparatus (Kovács *et al.*, 1998).

Another reagent (NBD-Cl), which itself is not fluorescent but forms fluorescent derivatives with primary and secondary aliphatic amines, seems to have advantages compared to dansyl chloride since it does not produce fluorescent products with phenols, thiols and anilines, or as a consequence of hydrolysis reactions.

Two-dimensional (2D) TLC allows the separation of nearly every mixture of interest. A comparative study of the chromatographic properties of derivatized biogenic amines with dansyl chloride, dansyl chloride and 4-chloro-7-nitrobenzoxazole shows that the dansyl chloride should be preferred in terms of both sensitivity and, to a lesser extent, resolution on silica gel by 2D-TLC. Dansylated and dansylated products were found to have similar TLC characteristics and were adequately resolved by eluting in the

Figure 2 Structures of the reagents used for derivative formation.

first direction with ethyl acetate–cyclohexane (3 : 2 v/v) and in the second with benzene–triethylamine (5 : 1 v/v). The plates were developed in the dark.

Aromatic Amines

Table 4 shows the hR_F values of several primary aromatic amines under different experimental conditions. Such compounds have been studied on silica-

gel G or alumina using organic and aqueous–organic solutions as eluents.

Further studies concern the chromatographic behaviour of aromatic amines on silica gel impregnated with silver compounds as π -complexing metal and manganese, cadmium and zinc salts as complexing agents. On silica gel impregnated with manganese salts, the pK_a values of the conjugated acids of sixteen isomeric methylanilines and chloroanilines

Sources: Adapted from Gillio-Tos M, Previtera SA and Vimercati A (1964) Separation of some aromatic amines by thin-layer chromatography. *Journal of Chromatography* 13: 571–572; Lepri L, Desideri PG and Heinler D (1979) Soap thin-layer chromatography of sulfonamides and aromatic amines. *Journal of Chromatography* 169: 271–278; Lepri L, Desideri PG and Coas V (1974) Chromatographic and electrophoretic behaviour of primary aromatic amines on anion-exchange thin layers. *Journal of Chromatography* 90: 331–339.

were correlated with their R_M values using benzene-ethyl acetate-acetic acid (2 + 2 + 1 v/v) as mobile phase. Separations via charge-transfer complexes with nitro compounds (picric acid, 2,4,6-trinitrophenyl-*N*-methylnitramine and 2,4-dinitrochlorobenzene) have also been reported.

Reversed-phase planar chromatography has been performed on silanized silica gel untreated or impregnated with cationic and anionic surfactants. The aromatic amines, which are in the free base form at the pH of the eluent, exhibit a high affinity towards the silanized silica gel and are more strongly retained in the presence of *N*-dodecylpyridinium chloride on the stationary phase.

As the pH of the eluent decreases, a sharp increase in the R_F values is observed on the impregnated layers (see Table 4, columns 3–5). Such behaviour is correlated with the protonation of one or more of the amino groups present in the aromatic amines. On the basis of hR_F values many interesting separations of isomers can be carried out.

Primary aromatic amines can be separated, with difficulty, on polystyrene-based cation exchangers in aqueous-organic solutions and also by elution with concentrated mineral acids owing to the high affinity of such exchangers towards compounds which contain one or more aromatic nuclei. Therefore weak cation exchangers, i.e., carboxymethylcellulose (H^+ or Na^+ form) and alginic acid, or synthetic inorganic exchangers such as ammonium molybdophosphate and tungstophosphate, have been used for separating such compounds. Better results can be achieved using polystyrene-based anion exchangers as shown by the hR_F values obtained on AG-1X4 (CH_3COO^-) plates (see Table 4, columns 6 and 7).

As regards the influence of the pH of the eluent, not that the protonated forms of the amines exhibit a lower affinity towards the exchanger than the free base forms.

An equation similar to that suggested for alkaloids can be used for studying quantitatively the influence of eluent pH on the chromatographic characteristics of aromatic amines:

$$(1/R_F) - 1 = (1/R_{F_{alk}} - 1)(K_a/K_a + [H^+]) + (1/R_{F_{ac}} - 1)([H^+]/(K_a + [H^+]))$$

where K_a is the dissociation constant of conjugated acid of the base and $R_{F_{ac}}$ and $R_{F_{alk}}$ are the R_F values of the protonated and the free base form of the amines, respectively.

The detection of aromatic amines has been accomplished with fluorescamine in glacial acetic acid (1 mg mL^{-1}), 5% *p*-dimethylaminobenzaldehyde in

a 5 : 1 mixture of ethanol and glacial acetic acid, 0.2% chloranil in chlorobenzene or 9-chloroacridine in 95% ethanol.

Diazotization and coupling can be carried out directly on the layer, i.e., the plates can be exposed to nitrogen dioxide to diazotize the amines and then sprayed with a solution of 0.1 M β -naphthol and 0.1 M triethylamine in benzene.

Derivatives of aromatic amines have also been used for separating and identifying these compounds. Therefore, 2,4-dinitrophenyl derivatives and dansyl derivatives have been studied on silica gel with different solvent systems.

Fifty-four aromatic amines used as antioxidants and/or antiozonants for elastomers have been separated on silica gel with a concentrating zone using benzene-ethyl acetate-acetone (100 : 5 : 1 v/v) and benzene-*n*-hexane (50 : 50 v/v) as eluents. The detection reagent is *N*-chloro-2,6-dichloro-*p*-benzoquinone monoimine in buffered alkaline medium.

Heterocyclic Bases

Heterocyclic compounds containing one or more nitrogen atoms have been extensively investigated on thin-layer chromatography as detailed in Table 5. Almost all the heterocyclics are chromatographed on polar stationary phases (silica gel, alumina, cellulose, polyamide) and, to a lesser extent, on hydrophobic layers obtained by impregnating polar adsorbents with nonpolar substances or by using silanized silica gel plates. Chemically modified and impregnated layers with cationic and anionic surfactants are also used.

Among the various types of 'simple' nitrogen heterocyclics, the separation of pyridines, indoles, quinolines and pyrimidines is of interest. The indole group of compounds is conventionally divided into the so-called simple derivatives and the indole alkaloids and dyes. A number of simple indole derivatives play important roles in physiological processes. Alkaline and acidic systems are employed on both silica gel and silanized silica for the separation of these compounds (see Table 6).

The two-dimensional technique on Sil C_{18} -50 plates can be performed by eluting in the first direction with *n*-hexane-ethyl acetate-acetic acid (72 : 27 : 1 v/v) and in the second direction with 0.1 M ammonia in 40% methanol. This technique allows the separation of 20 indole derivatives; the spots can be identified from their positions on the chromatogram and also from their colours obtained after spraying with 1% *p*-dimethylaminobenzaldehyde solution in concentrated hydrochloride acid-methanol (1 : 1) and heating the plates at 50°C for 20 min.

Table 5 Methods used for the separation of various types of nitrogen heterocyclics

Compound	Layer	Eluent
Azines	Alumina	Benzene–Chloroform (1 : 1)
Azines	Silica gel with or without a fluorescent indicator (F ₂₅₄)	CCl ₄ –EtOH–Me ₂ CO (50 + 1 + 2); <i>n</i> -PrOH– <i>n</i> -hexane in different ratios
Azines	Cellulose MN-300 F ₂₅₄ , Aminoplast	CH ₃ OH–H ₂ O–CH ₃ CN (30 + 20 + 5); CH ₃ OH–aqueous ammonia (30 + 20); CH ₃ OH–aqueous acetic acid (30 + 20)
Azines	Silica gel F ₂₅₄ impregnated with 5% paraffin oil in <i>n</i> -hexane	Water–organic solvents
Azines	RP-2, RP-8, RP-18	H ₂ O–CH ₃ OH in different proportions
Benzodiazepines	Silica gel and silica gel F ₂₅₄	CHCl ₃ –Me ₂ O–iPrOH and <i>n</i> -hexane–Me ₂ CO in different ratios; CHCl ₃ –Me ₂ CO (80 + 20); benzene; BuOH–CHCl ₃ –NH ₄ OH (50 + 50 + 1); BuOH–C ₆ H ₆ –NH ₄ OH (50 + 50 + 1 and 40 + 10 + 30); CHCl ₃ –MeAc (90 : 10); C ₆ H ₆ –iPrOH–25% NH ₄ OH (85 + 15 + 1)
Benzodiazepines	RP-18, KC18F	Acetate or phosphate buffer + CH ₃ OH or CH ₃ CN in different proportions
Benzodiazepines	Silica gel impregnated with oleyl alcohol	NaOH–aqueous buffer solutions (pH 9–9.5) saturated with oleyl alcohol
Benzoquinoxalinone derivatives	Silica gel 60 F ₂₅₄	CH ₂ Cl ₂ + EtAc (17 + 3)
Benzimidazoles and Benztriazoles	Cellulose F ₂₅₄ , starch F ₂₅₄	H ₂ O + CH ₃ OH or CH ₃ CN in different proportions
Carbazoles	Silica gel	Benzene; EtAc–MeOH–HCOOH–Pyridine (7.5–7.5–7.5–10); EtOH
Carbazoles	Alumina	Petroleum ether (40–60°C)–CHCl ₃ (10 : 1); petroleum ether–HAc (10 : 1)
Cyclic amidines	Silica gel F ₂₅₄	CH ₃ OH + CHCl ₃ or benzene in different ratios
Imidazolines	Silica gel	Benzene–Me ₂ CO–25% NH ₄ OH (4 : 17 : 1)
Imidazoles	Silica gel	CHCl ₃ –Me ₂ CO–HAc (34 : 4 : 3) EtAc saturated with NH ₄ OH
Indoles	Silica gel	BuOH–HAc–H ₂ O (2 : 1 : 1); Me ₂ O–HAc (100 : 1); phenol–H ₂ O (4 : 1); iPrOH–25% NH ₄ OH–H ₂ O (20 : 1 : 2) BuOH–EtOH–cyclohexylamine (76 : 3 : 6); Me ₂ CO–CHCl ₃ –HAc–H ₂ O (8 : 8 : 4 : 1); MeCOEt–CHCl ₃ –conc. NH ₄ OH (40 : 10 : 1); MeCOEt–CH ₃ OH–conc. NH ₄ OH; EtAc–iPrOH–conc. NH ₄ OH (45 : 35 : 20) BuOH–HAc–H ₂ O (12 : 3 : 5); benzene–dioxane–H ₂ O (1 : 1 : 1); benzene–pyridine–H ₂ O (1 : 1 : 1)
Indoles	Cellulose	CHCl ₃ –EtAc–HAc (7 : 2 : 1); CHCl ₃ –cyclohexane–BuOH–HAc–H ₂ O (1 : 1 : 1 : 1 : 0.2)
Indoles	Polyamide	H ₂ O–CH ₃ OH–HAc (59 : 40 : 1); 0.1 M NH ₄ OH in 40% methanol; <i>n</i> -hexane–EtAc–HAc (72 : 27 : 1); 0.1 M NH ₄ OH + 0.1 M NH ₄ Cl in 40% methanol; 0.5 M NH ₄ OH + 0.5 M NH ₄ Cl in 40% methanol; <i>n</i> -hexane EtAc–HAc (67 : 32 : 1)
Indoles	Sil C ₁₈ -50; Sil C ₁₈ -50 + 4% N-DPC	1 M NH ₄ NO ₃
Indoles	AWP	Octanol–petroleum ether (110–115°C) (1 : 5)
Indole esters	Silica gel	1 M NH ₄ OH + 1 M NH ₄ Cl in water or in various mixtures with methanol
Nitroimidazoles	Silica gel G F ₂₅₄ impregnated with a 5% solution of silicone oil in diethyl ether	
Piperazines	Silica gel	EtAc–CH ₃ OH (4 : 1); CHCl ₃ –CH ₃ OH–HAc (14 : 2 : 1)
Piperidines	Alumina	CHCl ₃ saturated with NH ₄ OH
Pyrazoles	Silica gel	EtAc (saturated with H ₂ O); CHCl ₃ –Me ₂ CO (7 : 3); MeCOEt
Pyrazolones	Silica gel	Cyclohexane–CHCl ₃ –EtOH (4 : 10 : 1); cyclohexane–MeCOEt (4 : 5)
Pyrazolidines	Alumina	
Pyridines	Silica gel	Benzene–MeOH (25 : 1); EtAc–MeOH–HAc (15 : 4 : 1); diethylether–dimethylformamide (99 : 1)
Pyridines	Silica + Ag ₂ O	Me ₂ CO–C ₆ H ₆ (2 : 3); MeCOEt–iPrOH (4 : 1); CHCl ₃ –CH ₃ OH (3 : 2)

Table 5 Continued

Pyridine derivatives	Silanized silica gel untreated or impregnated with sodium dodecylsulphate as ion-pairing reagent	Phosphate buffer solution-CH ₃ OH (1 : 1) with the buffer pH adjusted to the appropriate value (pH 3 to 10)
Pyrimidines	Silica gel	CHCl ₃ -CH ₃ OH (3 : 1)
Pyrimidines	Dowex 50-X4 (H ⁺)	0.25-4 M hydrochloric acid
Pyrimidines	Carboxymethylcellulose (Na ⁺), Dowex 50-X4 (Na ⁺)	Water; 0.1 and 0.5 M acetate buffer
Pyrroles	Silica gel	<i>n</i> -Hexane-CHCl ₃ (9 : 1); diethylether-2% HAc in <i>n</i> -hexane (1 : 1)
Pyrrole acids	Silica gel	CHCl ₃ -96% HAc (1 : 1); benzene-CH ₃ OH-HAc (45 : 8 : 4)
Quinolines	Silica gel	EtAc-iPrOH-NH ₄ OH (9 : 6 : 4); benzene-EtAc (1 : 1)
Quinolines	Silica gel 60HF ₂₅₄ , aluminium oxide, Florisil	Binary mixtures of <i>n</i> -heptane with polar modifiers (iPrOH; dioxane, EtAc, tetrahydrofuran MeCOEt, Me ₂ CO, iPr ₂ O, CH ₂ Cl ₂)
Thioindigoid thiazolidinones	Silica gel H	EtOH; CH ₃ CN; Et ₂ O; CH ₃ OH
Triazoles	Alumina	<i>n</i> -Hexane-benzene (1 : 1); 1% adipate in xylene-formic acid (49 : 1)

Tryptophan and some of its indole metabolites in urine (5-hydroxytryptophan, tryptamine, serotonin, indolyl-3-acetic acid and 5-hydroxyindolyl-3-acetic acid) have been separated by TLC, stained with van Urk's Salkowski reagent, and determined by scanning densitometry using indolyl-3-butyric acid as internal standard. Sep-Pak C₁₈ cartridges are used for extraction of metabolites from urine. The detection limits are 2 µg mL⁻¹ 5-hydroxytryptophan, 1.75 µg mL⁻¹ 5-hydroxyindolyl-3-acetic acid, 1.5 µg mL⁻¹ tryptophan, 0.8 µg mL⁻¹ indolyl-3-acetic acid, 0.9 µg mL⁻¹ indolyl-3-butyric acid, 1.75 µg mL⁻¹ serotonin and 1.25 µg mL⁻¹ tryptamine.

The chromatographic behaviour of several pyridine derivatives, some diazines and their sulfides, dimers and trimers has also been studied on both silica gel and silanized silica (see Table 7). The retention of azines and diazines in adsorption TLC on silica gel with *n*-propanol-*n*-hexane eluents can be calculated by the relationship adopted by Kowalska for reversed-phase chromatography:

$$R_F = A + B(X_1)^{1/2} + CX_2$$

where X₁ and X₂ are the volume fractions of alcohol and hydrocarbon, respectively, and A, B, and C the equation constants. In the reversed-phase systems on RP-2, RP-8 and RP-18 plates, R_M values were found to be linearly dependent on methanol concentration (binary methanol-water mixtures) showing the dependence of the retention values on the hydrophobicity and chemical structure of the analysed compounds.

A large number of pyrimidines (nucleobases included) have been studied on plates of silanized silica gel with different characteristics. The layers were also impregnated with anionic surfactants in order to

evaluate the role of the ion-exchange process on the chromatographic behaviour of these compounds (Table 8). The hR_F sequences of the pyrimidines under the various conditions are related to solvophobic effects, their acid-base characteristics, and the association of the species in solution.

Seven different thin-layer chromatographic systems were investigated to separate 19 pairs of the *E-Z* geometrical isomers of pyrimidine, purine and pyrazole derivatives with potential cytokinin activity. These systems employed silica, silanized silica, silanized silica/Cu(II) cation, chemically bonded RP-8 and RP-18 as stationary phases and a variety of binary mobile phases. The best performance was observed on silica gel with *n*-hexane-ethyl acetate 1 + 9 v/v as mobile phase.

For the location of heterocyclic bases, Dragendorff's reagent is usually employed; other detection agents are tetracyanoethylene and iodine-azide solutions.

Pyrazoles can be visualized with sodium nitroprusside; pyrazolones with 1% mercuric nitrate, iodine-potassium iodide or 10% ferrocyanide-12.5% hydrochloric acid (1 : 1); and imidazoles with iodo-platinate reagent. Indoles can be detected with Ehrlich's, van Urk's and Prochazka's reagents, or *o*-phthalaldehyde-sulfuric acid solution (0.15% w/v). A specific and sensitive fluorescent detection method was proposed for the analysis of nitroimidazoles (titanium (III) chloride followed by spraying with diazotized sulfanilic acid).

Miscellaneous Nitrogen Compounds

Because of the possible presence of nitroso carcinogens in foods, the separation and determination of

Source: Adapted from Stahl E and Kaldeuoe H (1951) Trace analysis of physiologically active, simple indole derivatives. *Zeitschrift für Physiologische Chemie* 323: 183–191; Lepri L, Desideri PG and Heinler D (1983) High-performance thin-layer chromatography of indole derivatives on layers of Sil C₁₈-50 untreated or impregnated with N-dodecylpyridinium chloride and on ammonium tungstophosphate. *Journal of Chromatography* 260: 383–389.

N-nitrosamines are of interest. Silica gel, magnesium silicate, cyano- and diol-bonded silica have been used as stationary phases to separate these compounds. Alkyl- and aryl nitrosamines can be separated on silica gel with *n*-hexane-diethyl ether-dichloromethane (4 : 3 : 2 v/v) and cyclic nitrosamines with the same solvent mixture in a ratio of 5 : 7 : 10 (v/v).

The chromatographic behaviour of 26 compounds derived from 1,1-diphenylhydrazine was investigated by normal and reversed-phase chromatography. The same techniques were used for the separation of several thiosemicarbazides and 1,2,4-triazoline-3-thiones on silica gel, alumina, and C₁₈-modified silica-gel layers, and nonaqueous and aqueous eluents.

Amides are physiologically active compounds and a knowledge of possible interactions of the amide

group and of different substituents under conditions close to those in physiological systems is highly important.

The separation of formanilide and ten para-substituted acetanilides was investigated on starch and cellulose layers, as an alternative to RP-18, using aqueous mobile phases with methanol, acetonitrile, acetone and 1-propanol as modifiers. Because R_M values are related to the partitioning of solute molecules in the given system, they can be regarded as a measure of solute hydrophobicity.

The retention behaviour of three series of aromatic amides was investigated on silica gel with eight binary solvent mixtures (benzene-CHCl₃ 20 : 30 v/v; benzene-ethyl acetate 45 : 5 v/v; benzene-acetone 45 : 5 v/v; benzene-dioxane 45 : 5 v/v; heptane-ethyl acetate 40 : 10 v/v; carbon tetrachloride with ethyl acetate, acetone or dioxane in a 45 : 5 v/v ratio). separated on silica-gel plates developed with methanol-pyridine-formamide, 80 + 15 + 5 (v/v) and detected with ninhydrin.

The lipophilicity of fused-ring nitrogen heterocyclic was determined by reversed-phase TLC on paraffin oil impregnated Silkoplat plates (Labor, MIM) using acetonitrile-aqueous solutions of different pH as eluents.

Lastly, amino-PAHs have been identified in sewage sludge after separation of the DMF extracts on a silicic acid column into three groups: carbazoles, aminoarenes and azaarenes. RP-18 F₂₅₄ (Merck) layers were developed with acetonitrile + water (9 : 1 v/v), observed under UV illumination at $\lambda = 254$ and 365 nm and then sprayed with specific reagents for detection of the amino group. Aminonaphthalene, aminoquinoline and/or aminoisoquinoline, amino-fluorene, aminoanthracene and/or aminophenanthrene,

aminopyrene, aminophenylanthracene and aminochrysene were found in the sludge.

Concluding Remarks

This article demonstrates the current possibilities for the separation of selected organic bases. Most attention has been devoted to the advantages of TLC, retention mechanisms, structure, sample preparation, mobile and stationary phases, usual modes of development and detection procedures, and also two-dimensional techniques.

Quantification of organic bases mainly by *in situ* densitometry has been described. The development of HPTLC and the potential for other innovations such as overpressured thin-layer chromatography (OPTLC) with this group of compounds is of considerable interest.

Introduction

Bile acids, a group of steroidal acids with a carboxyl group in the side chain, are the major end products of cholesterol catabolism, formed in the liver, conjugated with amino acids, glycine and taurine, and secreted into the bile. In most animal species, bile acids contain 24 carbons, with the terminal side chain carbon in the form of a carboxyl group; however, certain reptiles have 27-carbon bile acids as the major biliary bile acids. Primary bile acids are formed via the 5β -saturation of cholesterol double bond by hepatic enzymes, epimerization of 3β -hydroxyl group to α -configuration and further insertion of 7α - and/or 12α -hydroxyl group, shortening of the side chain by three carbons and oxidation of the terminal carbon to a carboxyl group. Structures of some of the bile acids found in animal species are shown in Figure 1. Bile acids facilitate the absorption of dietary lipids, including fat-soluble vitamins and cholesterol, via their detergent action. The detergent properties of bile acids result from their unique structure with a non-polar steroid skeleton and a polar carboxyl group and α -oriented hydroxyl groups, further increased by hepatic conjugation with glycine and taurine (Figure 1).

Bile acid conjugates form micelles with phospholipids that solubilize cholesterol in the bile. The primary bile acids, cholic acid and chenodeoxycholic acid, are effectively reabsorbed from ileum during their enterohepatic circulation, but approximately 5% that escape reabsorption seep into the colon, and are subjected to modification to secondary bile acids by intestinal bacteria. These modified bile acids, in particular the 7α -dehydroxylated bile acids, lithocholic acid and deoxycholic acid, are the major faecal bile acids and are also significantly absorbed from the colon and circulate in the enterohepatic circulation, with deoxycholic acid as one of the major plasma and biliary bile acids in humans. Whereas only small amounts of bile acids are excreted into the urine, approximately 500 mg per day is excreted in faeces and forms a major catabolic pathway for the elimination of body cholesterol.

In hepatobiliary and intestinal diseases, the hepatic synthesis and clearance of bile acids and their intestinal absorption are abnormal, which disturbs both cholesterol synthesis and its metabolism, causing increased plasma, urinary and faecal concentrations of bile acids. This results in accumulation of precursors of cholesterol or bile acids and clinical malformations ensue. Early diagnosis of such conditions is often possible from bile acid analysis in bile, serum, urine and faeces. On the other hand, bile acids have therapeutic applications in conditions of abnormal cholesterol biosynthesis and metabolism, and chenodeoxycholic acid, and its 7β -hydroxy epimer, ursodeoxycholic acid, are used for medical treatment of gallstones while ursodeoxycholic acid is also being

Figure 1 Structures of bile acids and their derivatives.

used in clinical trials for a variety of hepatobiliary diseases, including primary biliary cirrhosis, primary sclerosing cholangitis and hepatitis C, and is suggested to suppress colon polyp formation in experimental animals. Thus, bile acid analysis is an important diagnostic tool for diseases of the liver and intestine, and for monitoring bile acid therapy in such diseases. Of the several methods employed for bile acid analysis in biological fluids, gas chromatography (GC) has proven to be the most versatile and is sensitive enough to quantitate nanomole to picomole amounts present in biological specimens.

Choice of Column

For more than a decade, since the first application of GC for bile acid analysis by Vanden Heuvel *et al.* in

1960, GC was performed using metal or glass-packed columns. Introduction of capillary or open tubular columns was a major landmark in the development of GC. The separation of serum bile acids using capillary columns was first demonstrated by Laatikainen *et al.* in 1975 (Table 1). Coupled with the fact that the retention times are highly reproducible, capillary columns have fast become columns of choice for most chromatographic applications for bile acids. The usual capillary column is 25–50 m long with an internal diameter of 0.22–0.25 mm. The inner wall is coated with the liquid phase, which may vary from nonpolar (e.g. methyl silicones, such as OV-1, CP-Sil-5 CB and SE-30) to more polar (like phenylmethyl- and cyanopropylsilicone, e.g. CP-Sil-19 CB) depending on the need. Usually peaks are very sharp; however, the dead volume must be very small and

Table 1 Important advances in gas chromatography of bile acids

1965	Grundy <i>et al.</i>	Comprehensive method for faecal bile acid analysis using packed columns. Bile acids were isolated free from faecal fatty acids, sterols and other contaminants before chromatography. Method often used as a standard to which other methods are compared
1975	Laatikainen <i>et al.</i>	Introduction of capillary columns for serum bile acid analysis
1987	Child <i>et al.</i>	Simultaneous quantitation of faecal bile acids, sterols and fatty acids
1998	Batta <i>et al.</i>	Bile acid analysis was greatly simplified. Bile acids were derivatized and quantitated directly in the stool sample and the multiple steps of removal of sterols and fatty acids were avoided

only microgram or nanogram quantities of compounds can be injected in order to get appropriate peak shapes.

New instrumentation and use of splitless injectors have greatly reduced the dead volume while increasing the sensitivity, so that capillary columns are ideal for chromatography of trace compounds in biological fluids. Quantitation of bile acids in a sample is carried out by comparison of peak areas with those of known amounts of reference compounds in a range where a linear detector response is obtained. Usually a known amount of an internal and/or external standard is added to the sample to facilitate quantitation. Often a mass spectrometer is used as a detector for GC, and gas chromatography–mass spectrometry (GC-MS) has the added advantage that the mass fragmentation can give insight to the structure of the compound. The sensitivity of GC-MS is several-fold increased by using selected-ion monitoring, when picomole quantities of bile acids can be detected. Selection of the right internal standard is important for quantitation of bile acids using the mass spectrometer in the selected-ion mode. Often isotope-labelled bile acids (polydeuterated) are used, the advantage being that such compounds mix with the bile acid to be quantitated and are similarly extracted from the biological source. Otherwise, a bile acid with different GC retention time is employed, and peak heights are calibrated using known amounts of the compounds to be quantitated. The mass ion selected for quantitation is usually a high mass ion and with significant abundance.

Extraction of Bile Acids

Bile acids are present from 1–2 $\mu\text{g mL}^{-1}$ in plasma and urine to significant amounts in the intestinal content and as much as 80 mg mL^{-1} in the gall bladder bile. They are present in unconjugated form as well as conjugated with glycine and taurine or as sulfate/glucuronides, often in association with proteins, sterols and their esters, free or esterified fatty acids, bile pigments and water-soluble small mole-

cules, which may interfere in their analysis. It is often necessary to isolate and at least partially purify bile acids before preparation for GC. Plasma bile acids mainly exist as glycine and taurine conjugates and unconjugated bile acids are present in only small proportions. Plasma is usually passed through Sep-pak, a reversed-phase C_{18} cartridge, when proteins and most of the cholesterol are removed and bile acids and their conjugates are eluted with methanol. Other methods of concentrating bile acids include lipophilic anion exchange gel, diethylaminohydroxypropyl Sephadex LH-20 and, more recently, size exclusion chromatography using Sephadex G-75 gel. Some of these ion exchange resins are also employed for separation of various conjugated bile acids so that conjugation pattern is determined in the sample. The bile acid fraction obtained by any of these methods is treated with strong alkali (4 mol L^{-1} sodium hydroxide, 115°C at 15 psi pressure) to hydrolyse the conjugates; neutral sterols are extracted out with solvents and the free bile acids are then extracted with ether or ethyl acetate after acidification. Under these conditions, the glucuronides and sulfate esters are also hydrolysed, and a pre-step of solvolysis may not be necessary. As an alternative to alkaline hydrolysis, bile acid conjugates may be hydrolysed with the enzyme, cholesteryl glycerol hydrolase, while β -glucuronidase plus sulfatase is used to hydrolyse glucuronides and sulfates. In order to correct for losses during extraction, an internal standard is added before the hydrolysis step, while an external standard (usually 5 α -cholestane) corrects for detector responses of the various compounds. The appropriate internal standard is a bile acid that is not present in the bile acid mixture to be quantitated. Nor-deoxycholic acid and nor-cholic acid are usually used as internal standards, but other compounds like hyodeoxycholic acid and 7 α , 12 α -dihydroxy-5 β -cholanoic acid have also been employed.

Biliary bile acids are present predominantly as the glycine and taurine conjugates. Since they are present in high concentrations in the bile, only a few microlitres of bile are usually required for quantitation by

GC. Also, since bile contains only 1–2% of cholesterol, it is much easier to obtain pure bile acids free from cholesterol. Urinary bile acids are also present mainly in conjugated form, and only a few milligrams per day are excreted. However, in hepatobiliary diseases like primary biliary cirrhosis, urine may become a major pathway for bile acid excretion and sulfate conjugation of bile acids is increased. Again, bile acids need to be deconjugated before GC analysis and methods similar to those for plasma can be used to obtain urinary bile acid composition.

Faecal bile acids are mainly found in unconjugated form and the bile acid pattern is highly complex, due to bacterial deconjugation and extensive metabolism during intestinal transit. Most abundant of these secondary bile acids are deoxycholic acid and lithocholic acid, which are reabsorbed from the colon and further modified by hepatic enzymes and circulate in enterohepatic circulation. Whereas scores of metabolites of bile acids are formed in the colon, bile acids in the jejunum remain predominantly conjugated due to the absence of bacteria in the small intestine, and they therefore mirror biliary bile acids. A major difficulty in quantitative analysis of faecal bile acids is their strong binding with the bacterial debris in the stool, and quantitative extraction is difficult. Furthermore, in addition to bile acids, stool contains neutral sterols, including cholesterol and its bacterial metabolites and plant sterols and their bacterial metabolites, and also fatty acids. Several methods have been reported for bile acid extraction from faeces, and most are quite complex. Thus, one method involves continuous Soxhlet extraction of aliquots of homogenized stool with chloroform–methanol; the extracted bile acids are subjected to methyl ester formation followed by preparative thin-layer chromatography. Grundy *et al.* extracted neutral sterols from homogenized stool, deconjugated any bile acid conjugates with alkali and finally extracted bile acids with chloroform–methanol after acidification of the solution. After evaporation of solvents, the residue was chromatographed over Florisil and the purified bile acid fraction was subjected to methyl ester formation and then to preparative TLC to separate fatty acids. Bands due to bile acids were isolated and used for GC. In other methods, stools have been extracted with ammoniacal alcohol, methanol–hydrochloric acid, acetic acid–toluene, and bile acids extracted after removal of neutral sterols.

Derivatization of Bile Acids

Derivatization of Carboxyl Group

The carboxyl group in bile acids is most often converted into the methyl ester. Treatment with

Figure 2 Gas chromatography of bile acids. Chromatographic conditions are described in Table 2; CP-Sil-5 CB capillary column was employed. (A) *n*-Butyl ester-trimethylsilyl ether derivatives of standard bile acids. Peak identification, derivatives of: 1, nor-cholic acid; 2, lithocholic acid; 3, deoxycholic acid; 4, chenodeoxycholic acid; 5, cholic acid; 6, ursodeoxycholic acid. (B) Faecal bile acids in a healthy volunteer. Dried stool (10 mg) containing 20 μ g nor-cholic acid as internal standard was directly subjected to *n*-butyl ester followed by trimethylsilyl ether formation, dissolved in 200 μ L hexane and 1 μ L was injected into the GC column. Peak identification: 1–6, same as in (A); a, sitosterol, 3', isodeoxycholic acid; 7, 3-keto, 12 α -hydroxy-5 β -cholanoic acid; 8, 12-ketolithocholic acid (C) Plasma bile acids in a patient with lipid storage disease, sitosterolemia. Plasma (1 mL) containing 10 μ g nor-cholic acid as internal standard was used. Bile acids were enzymatically deconjugated and bile acids obtained by passing through Sep-pak. Bile acids were derivatized as *n*-butyl ester-trimethylsilyl ethers, dissolved in 100 μ L hexane and 5 μ L was injected into the GC column. Peak identification: 1–6, same as in (A); a, sitosterol.

^aA Hewlett-Packard model 6890 gas chromatograph equipped with a flame ionization detector and an injector with a split/splitless device for capillary columns was used. A chemically bonded fused silica CP-Sil-5 CB or CP-Sil-19 CB capillary column (25 m \times 0.22 mm i.d.) was employed and helium was used as the carrier gas. The column temperature was kept at 100°C for 2 min, then increased at a rate of 35°C min⁻¹ to a final temperature of 278°C.

^bRetention indices (Kovats values) were determined by previous injection of an alkane mixture under identical GC conditions.

diazomethane in ether converts bile acids instantly into their methyl esters. However, small amounts of methyl ethers are formed as artefacts, so alternative methods are often employed. Methyl esters are quantitatively formed with methanol-sulfuric acid or anhydrous methanolic hydrochloric acid. Alternatively, 2,2-dimethoxypropane-hydrochloric acid may be used for derivatization. In addition to methyl esters, ethyl, *n*-propyl, isobutyl and *n*-butyl esters have all been employed, the advantage being that the retention times of the bile acid derivatives are increased and, sometimes, resolution is improved. In particular, much better separations from neutral sterols can be obtained and, as shown in Figure 2, chemical removal of neutral sterols may be completely unnecessary with the use of butyl esters.

Derivatization of Hydroxyl Groups

The derivative of choice for the hydroxyl group is the trimethylsilyl ether and a variety of silylating reagents are commercially available for quantitative derivatization of even hindered and tertiary hydroxyl groups. Thus, *N,O*-bis(trimethylsilyl)acetamide, in combination with trimethylchlorosilane, can convert relatively unhindered hydroxyl groups into their trimethylsilyl ether derivatives and, when mixed with trimethyliodosilane, the reagent is highly potent and

can silylate hydroxyl groups in all positions. Bis(trimethylsilyl)trifluoroacetamide is equally reactive as *N,O*-bis(trimethylsilyl)acetamide but the reagent and the by-products are more volatile. The older silylating reagent, a mixture of 1,1,1,3,3,3-hexamethyldisilazane, trimethylchlorosilane and pyridine (3 : 1 : 9) is still commonly used for derivatization. Retention volumes of several common bile acid methyl ester-silyl ether derivatives on capillary

Figure 4 Gas chromatography of acetate-methyl esters and trimethylsilyl ether-methyl esters of bile acids. Chromatographic conditions are described in Table 2; CP-Sil-5 CB capillary column was employed. (A) Trimethylsilyl ether-methyl esters of bile acids. (B) Acetate-methyl esters of bile acids. Peak identification: 1, lithocholic acid; 2, deoxycholic acid; 3, chenodeoxycholic acid; 4, cholic acid; 5, 3 α ,6 α -dihydroxy-5 β -cholanoic acid; 6, ursodeoxycholic acid; 7, 3 α ,6 β ,7 α -trihydroxy-5 β -cholanoic acid; 8, 3 α ,6 α ,7 β -trihydroxy-5 β -cholanoic acid; 9, 3 α ,6 β ,7 β -trihydroxy-5 β -cholanoic acid.

columns of low and medium polarity are given in Table 2, while the chromatographic resolution of these derivatives of a number of bile acids with additional hydroxyl group at C₆ (present in several animal species and in patients with hepatobiliary diseases) is shown in Figure 3. Although trimethylsilyl ethers have gained general applicability in bile acid analysis, other silylating groups sometimes have advantages. Thus, dimethylethylsilyl and dimethylpropylsilyl ether derivatives have longer retention times than the corresponding trimethylsilyl ethers, while *t*-butyldimethylsilyl ether derivatives are very stable, and also show significantly longer retention times, so that often better resolutions can be obtained. Hydroxyl groups can

also be protected as acyl derivatives and formate, acetate and trifluoroacetate derivatives have all been employed for GC. These derivatives are often more stable than the silyl derivative and sometimes show better resolution, as seen in Figure 4. A one-step derivatization of the hydroxyl and carboxyl groups with heptafluorobutyric anhydride, also resulting in simultaneous hydrolysis of the glycine and taurine conjugates of the bile acids, has been reported.

Derivatization of Oxo Groups

Oxo bile acids are formed by bacterial modification of bile acids during their intestinal transit and are therefore found in the intestinal content. Quantitation of

oxo bile acids is beset with problems. Thus, oxo bile acids, in particular, 3-oxo bile acids, are vulnerable to rigorous alkaline hydrolysis conditions and therefore the much milder enzymatic hydrolysis of conjugates is preferred when oxo bile acids are suspected. Oxo bile acid methyl esters can be chromatographed without further derivatization (the hydroxyl groups in the partially oxidized compounds must be derivatized); however, sometimes artefacts are produced and it may be better to protect the oxo groups as the *O*-methyloxime or the dimethylhydrazone derivatives.

Summary

Detection and quantitation of bile acids are important in health and disease. Bile acid synthetic defects may arise from both defective cholesterol synthesis and metabolism; bile acid therapy may correct some of these abnormalities. GC has proved to be of vital importance in determination of bile acids in biological fluids. However, a complete GC analysis generally takes a long time. By appropriate column and derivatization selection, analysis time can be significantly reduced, but sample preparation for GC analysis is usually time-consuming. Combination of GC and mass spectrometry greatly aids in the characterization of unknown bile acids. In attempts to get additional information, Child *et al.* have developed a method to quantitate sterols and fatty acids together with bile acids in stool samples. Advantage is taken of the greatly increased retention times of the *n*-butyl ester-acetates of bile acids, so that sterol acetates are eluted earlier than all bile acids present and a group separation of faecal fatty acids, sterols and bile acids is achieved. In a further advancement of the method, Batta *et al.* have prepared *n*-butyl esters of bile acids directly in faecal samples, followed by trimethylsilyl ether formation. They showed that

faecal bile acids could be quantitatively derivatized and eluted from the faeces and bile acids could be quantitated in the presence of other faecal components. The method is also applicable to plasma bile acid measurement. Figure 2 shows plasma and faecal bile acids in a healthy volunteer determined as the *n*-butyl ester-trimethylsilyl ether derivatives. Since the extra steps of extraction of bile acids and their purification are eliminated, the method can easily be adapted for routine screening of samples for bile acid analysis.

Introduction

Bile acids, the major components of the bile fluid, play a significant role in lipid metabolism. After formation in the liver and storage in the gall bladder, the bile is secreted in the duodenum. Due to their

chemical structure, all bile acids tend to form micelles and serve as natural detergents. In addition, bile acids are co-factors of pancreatic lipases and are pivotal for the digestion and absorption of fats and fat-soluble vitamins.

The primary bile acids cholic acid and chenodeoxycholic acid are synthesized in the liver and during their enterohepatic circulation various modifications occur. Conjugation with the amino acids taurine or glycine as well as deconjugation, sulfation, glucuronidation and modification by intestinal

bacteria lead to numerous secondary bile acid structures. The biliary and serum bile acid pattern as such as well as the detection of several secondary bile acids in serum can serve as disease markers and are of interest in therapeutic monitoring.

In healthy individuals the bile acid concentrations in the gall bladder and in duodenal bile are in the upper micromolar up to millimolar range. The determination of faecal bile acids is, however, not hampered by their overall concentration but by the complex pattern of primary and secondary derivatives as well as by the nature of the matrix. Bile acid patterns in serum, which are for healthy individuals in the upper nanomolar concentration range, are much harder to determine.

A number of gastrointestinal disorders and hepatic or biliary diseases, e.g. liver cirrhosis and hepatitis, lead to increased serum and urinary bile acid levels and result in significant changes in the bile acid pattern. Since bile acids are the major products of cholesterol metabolism, they play an important role in research and development of lipid lowering drugs and therapies.

This is the reason why simple, reproducible and sensitive methods for detection, separation and quantitation of bile acid patterns in all kinds of biological matrices and body fluids are of increasing importance in the pharmaceutical industry as well as for clinical chemistry.

Liquid Chromatographic Methods

With enzyme-based assays or other analytical methods like radioimmunoassays either total bile acid concentrations or single bile acids can be detected. Gas-liquid chromatography is a commonly used method for bile acid analysis, however, it does not allow the detection of conjugated bile acids. Therefore, in order to achieve relevant diagnostic data with regard to changes in the bile acid pattern, other specific separation techniques have to be employed.

In early studies on liquid chromatography of bile acids, silica gel was a commonly used stationary phase. Other materials such as aluminium oxide or neutral polymers were also used for separations under gravity pressure. Various solvent systems, e.g. mixtures of light petroleum, butanol, glacial acetic acid and other organic solvents have been described, mostly in combination with thin-layer chromatography (TLC) as a detection method. With the systems described, the separation of different groups into conjugated/nonconjugated bile acids is possible, however poor sensitivity and insufficient selectivity are major drawbacks and make them unsuitable for routine diagnostics.

High Performance Liquid Chromatography (HPLC) Analysis

Separation

The development of sophisticated HPLC instrumentation and of precise pumps with low pulsation as well as improved sensitivity of the detection systems along with new column materials have made this technique well suited for routine laboratory work. Over the last 20 years, a number of different HPLC methods for determination of bile acids in all kinds of biological fluids have been published, each of them with special advantages and disadvantages.

Early HPLC work was based on polar column materials like silica gel and others. However, these were just adaptations from TLC and LC studies to higher pressure and were again limited in selectivity and reproducibility due to the nature of the matrix as well as the solvents used. It took the development of reversed-phase materials like octadecylsiloxane-modified silica to make HPLC the most commonly used analytical method in the bile acid field. Using nonpolar C_{18} materials, conjugated as well as nonconjugated bile acids can be separated satisfactorily. Reversed-phase materials tolerate most organic solvents and are stable over a pH range from 0 to 7. They also tolerate high pressures without changes in the column bed, and custom-made packing materials guarantee the required reproducibility of the analytical results. Therefore it comes as no surprise that almost all of the HPLC methods published for bile acid separation are based on reversed-phase applications.

The solvent systems described are normally based on organic solvents, e.g. acetonitrile or methanol, mixed with a buffer system. Buffers are based either on ammonium salts, ammonium acetate or ammonium carbamate, or on alkali phosphates.

Detection

The major challenge in bile acid analysis is their detection, particularly of unconjugated bile acids. Various methods have been described based on detection systems like UV absorption, refractive index, fluorescence, electrochemistry and enzymatic or chemical post-column derivatization. The most common and sensitive methods will be discussed here. Electrochemical and refractive index detection, due to their limitations in sensitivity and reproducibility, play only a marginal role in bile acid analysis.

UV detection The amino acids glycine and taurine make the whole group of conjugated bile acids detectable by UV absorption at 200 nm (**Figure 1**). This method limits the components of the mobile phase to

Figure 1 Separation of 10 conjugated bile acids by reversed-phase HPLC and UV detection at 200 nm: 1, taurocholic acid; 2, tauroursodeoxycholic acid; 3, glycocholic acid; 4, glycourso-deoxycholic acid; 5, taurochenodeoxycholic acid; 6, taurodeoxycholic acid; 7, glycochenodeoxycholic acid; 8, glycodeoxycholic acid; 9, tauroolithocholic acid; 10, glycolithocholic acid.

solvents with low UV absorption. As detection at low wavelength is sensitive to all kinds of impurities, efficient sample preparation especially of biological material with low bile acid concentration is recommended. Also high purity reagents for the preparation of buffers and ultra pure organic solvents are required. Taking this into consideration, all methods based on RP-HPLC with UV detection allow qualitative and quantitative separation of all conjugated bile acids with biological relevance by gradient elution. The detection limits are in the range from 40 to 60 ng and show some individual characteristics for the respective bile acids.

Lacking a characteristic chromophore and due to their chemical structure, unconjugated bile acids cannot be determined by UV detection with sufficient sensitivity under conditions comparable to their conjugated counterparts. One solution to this problem might be the addition of an ionic compound like hyamine®, tetrabutylammonium phosphate or decyltrimethylammonium bromide as counter ion to the mobile phase. Separation and detection are then based on the formation of ion pairs. Some reports suggest that this method increases the sensitivity as well as the selectivity of separation and detection so that UV determination of unconjugated bile acids in a range of 20–30 ng is possible. In contrast to that, detection limits for the conjugated forms are about three-fold lower. However, since other detection methods provide higher sensitivity and efficiency, ion pair chromatography is rarely used in bile acid analysis.

Fluorescence detection A method to increase sensitivity in determination of bile acids is fluorescence labelling and fluorescence detection. Two different systems to generate fluorescent bile acid derivatives are commonly used.

A relatively old method to quantify total bile acid concentrations is enzymatic detection by 3 α -HSD. Since all natural bile acids possess a hydroxyl group in the 3 α -position, by enzymatic dehydrogenation and via formation of nicotinamide adenine dinucleotide (NADH), spectrometric detection at 340 nm is possible. Going back to this principle, 'column reactors' containing immobilized 3 α -HSD have been developed. When connected with the separation unit, usually a C₁₈ column, each substance is enzymatically transformed and as one of the reaction products, NADH can be determined by fluorescence detection at 350–460 nm. This method allows detection of nearly all free bile acids having a 3 α -hydroxyl group independent from conjugation, but is not suitable for derivatives where the 3 α -hydroxyl group is esterified, e.g. by sulfation or glucuronization. In the analysis of biological samples, other steroids with free 3 α -hydroxyl group can influence the results. Application of the post-column derivatization method needs additional instrumentation for introduction of the enzymatic reagent.

On the other hand, several fluorescent agents for pre-column derivatization have been reported. One of the most reproducible and sensitive methods is based on 4-bromomethyl-6,7-dimethoxycoumarin (BMC) as derivatizing agent. BMC reacts with carboxyl groups by formation of fluorescent esters detectable at 340–460 nm. Therefore, unconjugated and glycine-conjugated bile acids can be labelled as well as all kinds of bile acid esters at the 3 α -hydroxyl group. Despite the high sensitivity – concentrations of less than 5 ng can be detected – the method has disadvantages. One major problem results from the fact that taurine-conjugated bile acids cannot be detected, due to the lack of a carboxyl group necessary for an ester bond. Samples containing high amounts of these conjugates, e.g. gallbladder bile, have to be treated with choloylglycylhydrolase for deconjugation before the total amount of the free acids can be measured, or an additional method for detection of taurine conjugates has to be employed. Though the BMC reagent will react with all components possessing a free carboxyl group, e.g. fatty acids, bile acids can be well separated and quantified by choosing an appropriate elution system and adequate sample pretreatment. The BMC derivatization reaction works with dicyclohexanocrown ether (DCCE). Because of that, potassium salts of the bile acids have to be prepared so that a further sample preparation step

can be carried out. An alternative, very sensitive method with a detection limit of less than 1 ng has been suggested, based on the formation of naphthyl ester derivatives. This labelling procedure also needs some careful preparation steps in order to obtain a good analytical sample for fluorescent detection. Nevertheless, pre-column fluorescence labelling seems to be suitable especially for samples containing low total bile acid concentrations, but also for samples with unconjugated bile acids as major components as in serum (Figure 2).

Detection by mass spectrometry The most sensitive technique by far for bile acid detection is the coupling of a suitable HPLC system with a mass spectrometer. Detection limits range from 1 to 5 pg. However, the prerequisite for the production of valid and reproducible data is high quality equipment, resulting in high initial costs. LC-MS coupling is the method of choice for the specific determination of low bile acid concentrations in all biological matrices or tissues. Mass spectrometry requires very small sample volumes and flow rates. For the HPLC separation a microsystem able to produce constant flow rates in the range of microlitres per minute is recommended. The use of standard HPLC systems is possible, but a precise flow-splitting device has to be used. This has the advantage that the main part of the eluate can be utilized for further determinations, e.g. UV detection, in order to achieve additional data for quantification. A high performance system allowing the baseline separation of all bile acids of interest is necessary to obtain best results from MS detection. Both isocratic and gradient elution are possible, and all kinds of bile acids, despite conjugation or other modification, can be detected. After sample pretreatment and purification to remove interfering substances no further steps such as deconjugation, derivatization or enzymatic treatment are required.

Different mass spectrometry systems are reported to be suitable for LC-MS coupling. HPLC-thermospray MS methods were reported earlier, but seem to be less sensitive and reproducible compared to other methods. Fast atomic bombardment (FAB) MS and electrospray ionization (ESI) MS have been interfaced with HPLC and good results in reproducibility and sensitivity have been reported.

A special type of a mass detection system is the evaporative light-scattering mass detector (ELSD). A special feature of this detection method is that the eluate coming from the column is evaporated, and nonvolatile components such as bile acids are determined by measurement of the light deflected. The detection unit consists of a photodiode and a laser beam. When nonvolatile compounds pass through

Figure 2 Separation of 10 unconjugated and glycine conjugated bile acid derivatives (pre-column fluorescence derivatization with bromomethoxycoumarin) by reversed-phase HPLC and fluorescence detection: 1, glyoursodeoxycholic acid; 2, glycocholic acid; 3, glycochenodeoxycholic acid; 4, glycodeoxycholic acid; 5, ursodeoxycholic acid; 6, cholic acid; 7, glycolithocholic acid; 8, chenodeoxycholic acid; 9, deoxycholic acid; 10, lithocholic acid.

the laser, light scattering appears and can be detected. The signal is dependent on the molecular mass of the separated substance. The ELSD technique seems to be moderately sensitive with respect to UV detection but detects all bile acids and their derivatives as well as other analytes of interest. However, isocratic elution systems are required and, therefore, ELSD detection is only applicable in niche areas of application.

Detection of Bile Acids in Biological Samples

Bile The determination of the bile acid pattern in gallbladder or intestinal bile does not need a time-consuming sample pretreatment or enrichment. The bile fluid of mammalian individuals consists mainly of glycine- and taurine-conjugated bile acids in relatively high concentrations compared to other body fluids such as serum or urine samples. Therefore, HPLC separation with UV detection is the commonly used method for analysis of samples derived from bile. In the bile fluid of healthy individuals only small amounts of protein are present and do not interfere with bile acid detection. Therefore, no deproteination procedure is necessary. However, in order to remove small amounts of protein as well as cell debris and larger particles, the addition of methanol followed by a centrifugation step is recommended. For conventional analysis, dilution with the mobile phase and filtration through a microfilter is sufficient as sample pretreatment. The use of a guard column in the HPLC

system is recommended when larger sample quantities are to be analysed.

Faeces Problems in the analysis of bile acids in faeces are not caused by the total amount of bile acids but by the complexity of the faecal matrix. Since the primary bile acids in gallbladder bile and in the intestine are modified by the intestinal microflora during enterohepatic circulation, in faeces mainly secondary unconjugated bile acids are found. Time-consuming extraction procedures have been suggested, e.g. Soxhlet extraction or the use of alcoholic alkali solutions. Homogenization of the material in a mixture of chloroform and methanol using an ultraturrax mixer, followed by further purification with solid-phase extraction cartridges for sample pretreatment as described for serum preparation, seems to be able to extract most faecal bile acids quantitatively. Methods for pre-column fluorescence labelling, e.g. with bromomethoxycoumarin derivatives, are reported. For these derivatization procedures, sample pretreatment with choloylglycylhydrolase for deconjugation is recommended. In addition, detection with an evaporative light-scattering detector can be applied, with the advantage that a mass sensitive detection system is not limited by modifications in bile acid structure. However, the method suffers from nonspecific matrix products influencing the signal to noise ratio and hampering bile acid detection.

Serum and urinary samples The extraction, detection and quantification of bile acids in serum samples of healthy individuals is the most ambitious goal in the field of bile acid analysis. However, since changes in serum pattern can be characteristic for several metabolic and cancer diseases, considerable efforts have been made to develop methods of high sensitivity and reproducibility as tools for diagnostic purposes. Due to the nature of the matrix and to total bile acid concentrations in the low micromolar range, a sophisticated sample pretreatment procedure is absolutely necessary. The commonly used method for extraction and purification of serum samples employs solid-phase extraction as described by Setchell *et al.* Reversed-phase C₁₈ cartridges are activated with methanol and water as recommended by all manufacturers of these columns. Sodium hydroxide solution is added to the serum samples and is followed by a 15–30 min heating step where samples are incubated at 64°C to suppress protein binding. The resulting solution is passed through the activated C₁₈ cartridge where the bile acids should be retained while the matrix components are found in the eluted solution. Washing steps with water, in some cases followed by nonpolar organic solvents such as n-hexane,

are carried out. Bile acids are recovered by elution with methanol. In most cases, eluted samples are dried and redissolved in a small volume of the mobile phase used for HPLC separation. In some reports an additional purification step by anion exchange cartridges is described.

Despite the fact that this sample preparation method has been commonly used over a number of years it suffers from several disadvantages. The major problem is the relatively strong binding of bile acids to serum proteins. Incubation at higher temperatures leads to protein denaturation but does not release the bile acid binding sufficiently and reproducibly. Another approach is the enzymatic digestion of serum proteins. However, this method seems to be limited, since the products of the protein digestion, small peptides and amino acids, interfere with further HPLC detection. Recent work describes a deproteinization procedure by adding serum samples slowly to acetonitrile and incubating them in an ultrasonic bath for some minutes. This efficiently prevents co-precipitation of proteins and bile acids and secures reliable and validated analytical data. Another point has to be considered if solid phase extraction is applied as a sample pretreatment. C₁₈ column materials are offered by several manufacturers and differ in their quality and their respective features. For instance, endcapped and non-endcapped C₁₈ phases are offered commercially. These materials can differ in the quantity and the selectivity of bile acid retention. This leads to remarkable differences in bile acid pattern for the sample when different C₁₈ cartridges are used. Therefore, the results obtained can only be validated when exactly the same material, i.e. same specifications, batch, etc., is used.

An interesting method for automation of the sample pretreatment procedure has been described by Yoshida *et al.* The online purification, concentration and separation of bile acids in serum samples is performed by an HPLC device equipped with three columns. First samples are injected on to a hydroxyapatite column to remove serum proteins. For further purification and concentration, a second pre-column (Serumout-25®) is used. After washing and elution from this column the bile acids are injected via an injection valve to the reversed-phase separation column. This strategy of sample pretreatment might be of value for high throughput assays, e.g. in clinical diagnostics. However, it leaves the problem of protein binding unsolved and, therefore, lack of sensitivity and efficiency is expected.

In urinary samples almost the same problems as in serum bile acid analysis occur. In contrast to blood samples, the urine from healthy individuals does not contain proteins and is available in much

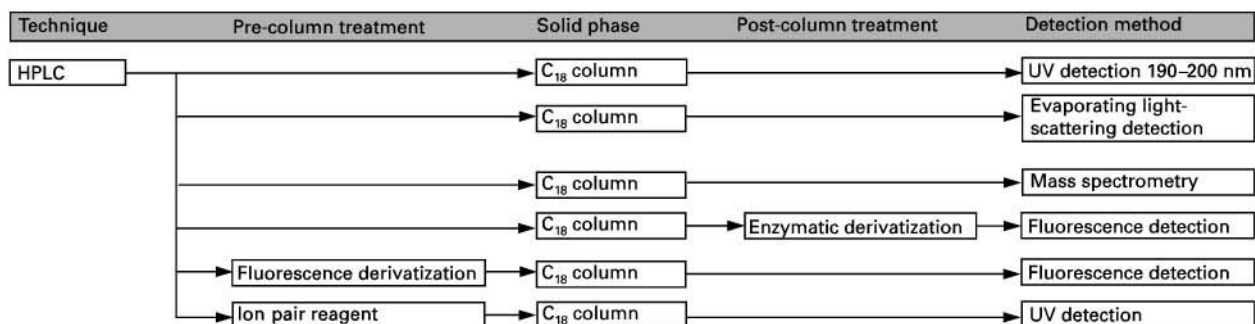

Figure 3 Separation methods for bile acids by liquid chromatography.

higher quantities. For these samples the standard purification procedure using C₁₈ solid-phase extraction is suitable.

Due to the low concentration range of the bile acid pattern in serum and urine, the methods of choice for quantitative and reproducible determination are pre-column fluorescence derivatization and HPLC-MS coupling.

Conclusion

With regard to the liquid chromatographic methods described for bile acid analysis, especially with regard to their determination in biological matrices, several approaches for qualitative and quantitative determination have been described. A critical evaluation of the advantages and disadvantages of these methods results in the conclusion that there are specific limitations for every application (**Figure 3**). Since cumbersome derivatization steps as well as laborious and unsuitable sample pretreatment play a key role in the value of the analytical results, technologies are needed where direct analysis of the bile acid pattern, especially in serum, is feasible. Only HPLC-MS coupling presently allows such analysis, but costly equipment and highly skilled personnel requirements limit this method to highly specific problems and makes it unsuitable for routine work.

Presently, HPLC of bile acids is state-of-the-art and only incremental improvements can be expected

from new column materials and microcolumns (\varnothing 1–2 mm). The future will be in the area of low cost, high throughput HPLC-MS devices for routine use.

Introduction

Gall bladder bile is, like other physiological fluids, of very complex nature. It is produced by liver

hepatocytes of healthy human beings in a volume of 500–1000 mL per day. The major function of the bile fluid is to support digestion and resorption of lipids and lipophilic substances during intestinal passage. In this respect, bile acids and their different conjugates are the most important components. Bile acids are steroids of amphophilic nature and, owing to their chemical structure, tend to form micelles and serve as physiological detergents. It is this feature that makes bile acids so important in their role in emulsifying fatty food components. In addition, bile acids serve as enzyme cofactors and support fat digestion by activating lipases and other factors of lipid metabolism. Humans, together with some other animals, possess a gall bladder in which bile fluid is stored. The human gall bladder has a capacity of 15–20 mL of concentrated bile. When bile is needed for digestion excretion into the gut is triggered by cholecystokinin, a gastrointestinal hormone which causes ejection of gall bladder contents. In the gall bladder bile is concentrated five- to ten-fold, leading to increased concentrations of all major bile components. Total bile production as well as bile composition are highly dependent on amount and composition of food. For example, according to differences in eating, the pH values of human bile range from 6.5 to 8.5. Other animals, such as rats, secrete bile fluid directly into the intestine.

The most important bile components are the bile acids and their different amino acid conjugates. Bile acids are synthesized in the liver from cholesterol and therefore play an additional key role in cholesterol homeostasis. Products of this process are the so-called primary bile acids cholic acid and chenodeoxycholic acid. In the bile fluid mainly glycine and taurine conjugates of these primary bile acids as well as those of deoxycholic acid are present. However, after secretion into the gut primary bile acids are modified by the intestinal microflora. Primary bile acids and all their derivatives produced during intestinal passage undergo enterohepatic circulation, by which bile acids are reabsorbed nearly completely and are transported back to the liver. Only a very small part of the bile acid pool, 2–8%, is excreted with the faeces. Nevertheless, the bile of healthy individuals contains more primary than secondary bile acids. As changes in total bile acid amount as well as in the bile acid pattern are of importance for diagnostic purposes, simple and fast methods for the analysis of these biological compounds are required (Figure 1).

Many drugs and drug metabolites are secreted into the bile, and this, in addition, makes bile analysis important for the understanding and controlling of pharmacokinetic mechanisms during drug development. Several methods using high performance liquid

Figure 1 Thin-layer chromatogram of gall bladder bile from several animals, and of human T-drainage bile; comparison with selected standard bile acids. (From Müller *et al.* 1992.)

chromatography (HPLC) and thin-layer chromatography (TLC), have been described for the analysis of pharmacologically interesting substances and their metabolites in bile, but as the analytical conditions are always dependent on the chemical nature of the drug and its concentration, they will not be considered here. Another bile component, cholesterol, has become increasingly important during recent decades. The role of increased serum cholesterol concentrations in diseases such as atherosclerosis, leading to stroke and cardiac infarction, for example, is the subject of debate, but when added to other risk factors its involvement is undisputed. Cholesterol concentrations in gall bladder bile range from 1 to 15 g L⁻¹ in humans. Increased bile cholesterol concentrations in most cases cause the formation of gallstones through cholesterol crystallization. The development of drugs influencing either serum or bile cholesterol concentrations is one of the most important areas in pharmaceutical research. Therefore, also in this field fast and simple methods for the detection and quantification of cholesterol in bile are necessary (Figure 2).

Bile fluid also contains high concentrations of phospholipids, especially lecithin, in amounts of 2–4 g L⁻¹. However, whether increases or decreases in phospholipid concentration are significant for

Figure 2 Composition of (A) human T-drainage bile (water content 95.5%) and (B) bovine gall bladder bile (water content 81.5%). (From Müller *et al.* 1992.)

differential diagnosis of certain enterohepatic diseases is not known. Nevertheless, the analysis of phospholipid pools and pattern in bile can be of value for metabolism and kinetic studies in drug development. Several TLC-based methods for separation and detection are known. Other bile components, such as bile pigments, proteins (e.g. alkaline phosphatase) and electrolytes, have to be analysed by other analytical methods (e.g. enzyme assays or spectrometric methods). In general, biliary protein concentration is negligible in healthy individuals (Figure 3).

Thin-Layer Chromatography

Bile Acid Separation

In contrast to other analytical technologies such as HPLC and gas chromatography, which are also com-

monly used for bile acid analysis, TLC is a very simple and nearly universal method. No highly sophisticated and expensive instrumentation is needed for reliable semiquantitative analysis. If precise quantification is essential, a TLC scanner equipped with a computer software system for fast and easy data registration and evaluation is recommended. Whereas HPLC analysis is limited by the fact that only one sample can be analysed at a time, TLC allows multiparallel analysis of probes in combination with an almost unlimited number of detection and visualization methods.

Several solvent systems for the separation of bile acids in biological fluids are described. With respect to bile, bile acid concentrations are in the millimolar range and therefore no detection problems occur, which makes TLC well suited for bile and bile acid analysis. In addition, time-consuming sample pretreatment procedures can be generally avoided for standard analysis of bile acids. However, dilution of the bile samples with phosphate-buffered saline increases the sensitivity of the selected detection (Figure 4).

For bile acid pattern analysis a satisfactory separation of the main components, the glycine- and taurine-conjugated bile acids, is necessary. In general, silica gel TLC plates are used for routine analysis since high quality materials are commercially available in several sizes and from several suppliers and, in contrast to reversed-phase plates for example, at a relatively low price. Our experience in this field leads us to suggest the use of silica gel pre-coated on glass plates with a concentration zone to improve separation, bile acid band shape and overall resolution. Solvent systems suitable for the separation of bile acids on silica gel are shown in Table 1. Many methods for bile acid separation have been described in the literature, and only a selection are shown here.

System 2 leads to the most satisfactory results in resolution and band shape. With this system the glycine and taurine conjugates of deoxycholic acid and of chenodeoxycholic acid can be separated with good resolution. The TLC plates have to be developed six times in the same solvent mixture for bile acid separation and this requires more time compared with the other solvent systems described, but if quantification by TLC scanning is followed system 2 is the method of choice. Solvent system 3 provides a simple and fast method for the separation of conjugated and unconjugated bile acids with sufficient overall resolution to allow quantification. The advantage of this system is the simultaneous separation of cholesterol, which migrates faster than the bile acids. Chamber saturation before analysis increases resolution and improves band shape. With system 4, a solvent

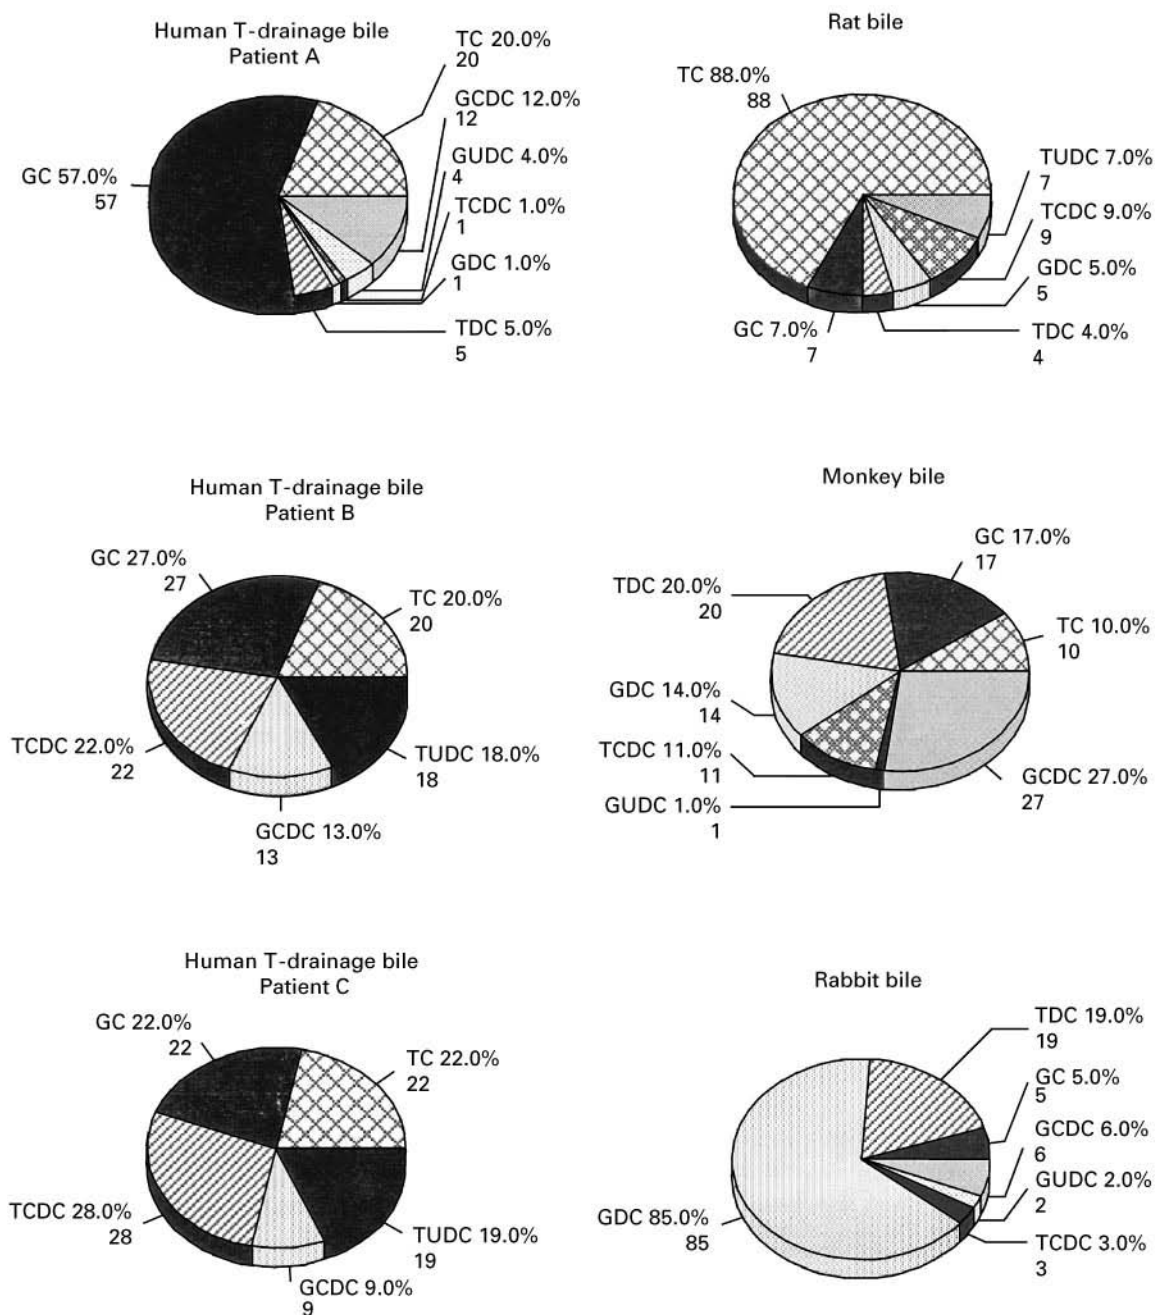

Figure 3 Bile acid patterns obtained from three samples of human T-drainage bile and from the bile of other animals. Key as for Figure 1, plus GDC, glycodeoxycholic acid and TDC, taurodeoxycholic acid. (From Müller *et al.* 1992.)

mixture for the separation of conjugated bile acids on reversed-phase TLC plates is provided. TLC conditions are similar to an HPLC method described for the separation of conjugated bile acids, and may be helpful in comparison of sample analysis by different analytical techniques or in cases where simultaneous separation of bile acids and drug metabolites is required.

In all the separation systems described temperature plays an important role in resolution.

Although room temperature (20–22°C) allows satisfactory separation employing the systems described, in some cases decreasing the temperature improves separation and band shape. Depending on the sample concentration and composition the influence of temperature on separation resolution should be taken

Figure 4 (A) Thin-layer chromatogram of increasing amounts (1, 2 and 4 μL of 4 mg mL^{-1} solutions) of bile acid standards TC, GC, TLC, GCDC, C, GLC, UDC and LC. (B) Fluorescence scan of the left lane of the chromatogram. Key as for Figure 1. (From Müller *et al.* 1992.)

into account as a critical factor for optimization of the chosen solvent system.

Numerous detection methods for bile acid visualization on TLC plates after separation have been described and two principally different systems are in use. Detection methods using reagents which form coloured complexes have the advantage that bands can be visualized directly. A universal detection re-

agent for a vast amount of biological substances is anise aldehyde dissolved in sulfuric acid. Spraying or dipping of the developed TLC plates followed by incubation at 125°C generates spots of different colour which are stable for some time. However, the low specificity of this reagent may cause problems in the analysis of samples with a high content of other components or analytes. Spots can also be visualized under ultraviolet (UV) light, which increases sensitivity. Individual bile acids can be identified by their different colours (Figure 5).

Molybdotophosphoric acid is another reagent often used for detection of biological components and forms blue bands on a yellow ground. Since colour intensity of the visualized spots is not stable over a long period of time, quantification must follow immediately after development of the colour.

The sensitivity of detection of bile acids on TLC plates can be increased dramatically by using a reagent system which forms fluorescent bands. HClO_4 has been described as giving reproducible fluorescent spots with bile acids on TLC plates, provided a 5% solution of this derivatizing agent is used and UV light of 365 nm excitation wavelength is employed after spraying and appropriate treatment at higher temperature.

According to our experience a reagent mixture of manganese dichloride and sulfuric acid is preferred for detection, owing to the reproducible results and its convenience in use. Plates are dipped in the reagent

and heated to 110°C for 10–15 min. Bile acids react with the reagent with the formation of yellow or brown coloured spots. Under UV light (365 nm) blue or yellow fluorescing bands can be detected. Bile acids can be differentiated by their respective colour. The detection sensitivity for the bile acids under UV con-

ditions is 2–5 ng and is therefore about 1000-fold higher compared to visible light (Figure 4).

Cholesterol

Cholesterol and cholesterol esters are important bile components. Several solvent systems for the

Table 2 Solvent systems for separation of cholesterol and cholesterol esters on silica gel plates

<i>System 1</i>	Room temperature

separation of these steroids exist, but only some of them are suitable for the analysis of cholesterol in complex biological fluids. In **Table 2** four commonly used methods are shown. The mixture of chloroform and acetone is described for the detection of cholesterol in serum samples and can successfully be adapted to bile analysis. In system 4 three organic solvents with decreasing polarity are suggested for three consecutive development steps and can be used in automated multiple development devices.

If simple and fast one-step analysis of cholesterol and bile acids is required, solvent system 1 combined with the above described manganese detection reagent should be used, since cholesterol can be separated and identified easily by fast migration and its orange fluorescence. Other staining reagents containing either trichloroacetic acid or 8-anilinonaphthalene-sulfonic acid ammonium salt have been shown to react with cholesterol to fluorescent bands, and numerous other universal detection systems are described in the literature. Adaptation to bile analysis seems to be possible in most cases.

Use of the NCS reagent (1,2-naphthochinone-2-sulfonic acid sodium salt) leads to purple bands which can be easily detected and quantified with detection limit at 5 ng cholesterol.

Phospholipids

As for the other bile components, several solvent systems for separation of phospholipids are known. However, most of them were not developed for the analysis of bile samples, but for other biological ma-

terials or mixtures of purified standard compounds. Due to the fact that the most abundant phospholipid in bile samples is lecithin, three solvent systems able to separate phosphatidylcholine, phosphatidylethanolamine, phosphatidylserine and phosphatidylglycerol are shown in **Table 3**.

Some of the most commonly used and versatile detection reagents described in the sections above are also suitable for phospholipid detection both under UV and visible light. Detection with the 2,7-difluorescein reagent increases sensitivity and allows reliable and satisfactory quantification. Detection by a reagent mixture containing ammonium molybdate, sulfuric acid and ascorbic acid results in blue bands which can be easily detected and quantified by a TLC scanning device at a wavelength of 620 nm.

Conclusion

For decades, TLC has proven its advantages as a fast, inexpensive, reliable as well as highly reproducible technology in the analysis of bile, bile acids and bile acid derivatives. Especially in bile acid and cholesterol analysis several separation and detection systems have been developed which have shown convincing sensitivity and overall resolution.

Solvent systems allowing the simultaneous detection of bile acids, cholesterol and drug metabolites in a one-step analysis give a significant time advantage at reduced cost. In addition, the separation system and overall conditions can easily be adapted to the respective analytical problem in most cases.

Although the quantitative detection of phospholipids in bile does not play a key role in bile

analysis at the moment, there is still a need to develop accurate TLC methods for detailed separation of these lipids. Further investigations on the use of new TLC materials in the quantitative analysis of bile components are needed, as well as the adaptation of TLC methods to automated devices. Nevertheless, compared to other analytical tools TLC is the method of choice for fast routine use.

BIOANALYTICAL APPLICATIONS: SOLID-PHASE EXTRACTION

D. A. Wells, Sample Prep Solutions Company,
Maplewood, MN, USA

Copyright © 2000 Academic Press

Introduction

The quantification of drugs and metabolites in biological fluids (e.g. plasma, serum and urine) is one of the most active research fields in clinical and pharmaceutical analysis. Drug bioanalysis is important in clinical chemistry to demonstrate optimal drug therapy, because plasma drug concentrations relate to the therapeutic or toxic effects of a drug. Knowledge of the plasma drug concentration is used to determine why a patient does not respond to drug therapy or why a drug causes an adverse effect. Dosage adjustment by the physician is then warranted. Drug bioanalysis is important in pharmaceutical research to determine the pharmacokinetics and metabolic biotransformation of new drug molecules. It is a technique used throughout the development of all new drugs. In particular, during drug discovery, bioanalysis yields essential data that is used in the decision-making process of whether or not a new molecule should be a candidate for further development.

This chapter discusses the utility of solid-phase extraction (SPE) in comparison with other drug sample preparation techniques for bioanalysis. Several applications of SPE will be summarized in the clinical setting for therapeutic drug monitoring, and in the pharmaceutical research setting for drug discovery and development. The separation and detection techniques used for bioanalysis will be

examined, contrasting the use of high-pressure liquid chromatography (HPLC) in the clinical setting and the rapid proliferation of HPLC combined with tandem mass spectrometry (liquid chromatography/mass spectrometry/mass spectrometry or LC/MS/MS) for specific and sensitive detection of drugs for pharmaceutical bioanalysis.

Drug Sample Preparation Techniques

A reliable analytical method is achieved with efficient sample preparation, adequate chromatographic separation, and a sensitive detection technique. Detailed and exact guidelines exist for the validation of bioanalytical methods, which meet requirements agreed to by the Food and Drug Administration. The sample preparation step is an important component of each overall bioanalytical method, as it

- often concentrates an analyte to improve its limits of detection,
- removes unwanted matrix components that can cause interferences upon analysis, thus improving method specificity, and
- frees the analyte from matrix components so that it can be placed into a solvent suitable for injection into the chromatographic system.

Liquid/liquid extraction

A common sample preparation procedure used to isolate drug analytes from biological matrices is liquid/liquid extraction (LLE). It is quite effective at removing salts and proteins; water-soluble endogenous components often remain in the aqueous phase.

The organic phase containing the extracted analyte is isolated, evaporated to dryness, and reconstituted in liquid chromatographic mobile phase for analysis. One of the benefits of LLE is that with proper selection of solvent and pH, very clean extracts can be obtained with good selectivity for the target analytes. However, the disadvantages of LLE are that

- it is a very labour intensive procedure,
- it requires large volumes of organic solvents which can be expensive to purchase and dispose,
- exposure of personnel to these solvents can be hazardous to health,
- it cannot easily be automated,
- emulsions have been demonstrated to occur,
- evaporative losses can occur upon dry-down with volatile analytes.

Despite its drawbacks, LLE continues to be used for drug bioanalysis when there is adequate labour and its associated costs are not prohibitive, and the sample throughput can be adequately met.

Protein precipitation

A fast and simple method of sample preparation is protein precipitation, also referred to as 'dilute and shoot'. This nonselective technique involves adding a water-miscible organic solvent (e.g. acetonitrile) or inorganic acid (e.g. trichloroacetic acid, 10%) to the biological matrix (usually in a 3 : 1 or 4 : 1 ratio, v/v), centrifuging or filtering to remove precipitated proteins and injecting an aliquot of the diluted supernatant. This technique is often performed in pharmaceutical drug discovery laboratories as the first attempt to prepare samples for bioanalysis. Satisfactory analyses have been demonstrated with this rapid sample preparation approach, but it has disadvantages. This technique dilutes the sample by a factor of four or five, so it is useful only when sample levels are relatively high, typically in the low $\mu\text{g mL}^{-1}$ range. Also, matrix components are not efficiently removed, and thus may co-elute with the analyte in the isolated supernatant or filtrate. When present, these contaminants have been shown to interfere with detection techniques and lower the signal for the analyte of interest. This approach thus lacks selectivity and problems can arise from column fouling since the precipitation efficiency is not complete.

Solid-phase extraction

Solid-phase extraction has, during the last 18 years, become recognized as a preferred technique for extracting drug analytes from complex biofluids using adsorption chemistry. The attraction of the analyte for a solid phase adsorbent ('sorbent') is exploited to

the exclusion of other compounds through a selective wash step. Elution of the analyte is achieved with an organic solvent that disrupts the attraction to the solid sorbent. Solvent exchange is followed by analysis on a chromatographic system. The traditional format for SPE has been single disposable columns and cartridges. Its advantages are that multiple samples can be prepared in parallel, low volumes of solvents are used and procedures can be readily automated. The technology has been improved in recent years with the introduction of more selective solid sorbent chemistries, disc-based SPE devices, smaller bed mass sorbent loading, on-line SPE techniques and introduction of the 96-well plate format for improved productivity.

An on-line SPE technique has recently shown great utility. A commercial device (ProspektTM (Spark Holland)) combines an autosampler and a solvent delivery unit to aliquot liquid samples into the flow path of solvent. An SPE cartridge is preconditioned and is in-line with the solvent flow. The cartridge retains target analytes while a weak solvent elutes unretained salts and polar matrix components. An optimized sequence of solvents, each with increasing solvent strength, is used to wash out weakly retained components. A final elution with LC mobile phase elutes the analytes of interest from the SPE cartridge and onto an analytical column for chromatographic separation followed by detection.

The autosampler within this device can be preloaded with up to 160 samples and the entire tray can be analysed in an automated procedure. Its advantages are: unattended sample prep and analysis, minimized adsorptive losses, since sample transfers are not performed as in off-line techniques, and trace enrichment of analyte occurs. Some disadvantages are that analysis is serial (although a sample is always being analysed while another is being extracted and prepared for injection) and sample stability may be an issue for some drugs as a result of extended storage times in the autosampler.

Therapeutic Drug Monitoring

Therapeutic drug monitoring (TDM) is an established clinical specialty in which laboratory specialists quantify drug concentrations for the purpose of evaluating therapeutic response. Examples of drugs that are frequently subjected to TDM are antibiotics, antiarrhythmics, antiasthmatics, antidepressants, antiepileptics, and antineoplastics. These drugs possess a narrow range of therapeutic and safe plasma concentration. Therapeutic index (TI) is defined as the ratio between the maximum and minimum plasma concentrations of the drug's therapeutic

range. A narrow range is defined as a ratio of 2 to 3. A TI below 2 infers that the dose that yields a subtherapeutic response is close to the dose that produces toxicity. Most drugs have a TI of greater than 2.

The preferred technique for drug analysis is use of an immunoassay analyser (e.g. fluorescence polarization immunoassay, FPIA) because it is relatively quick, can be automated, and requires minimal technician training for execution. However, newer drugs requiring plasma quantification often do not have an immunoassay developed, so chromatography is almost always used at first. Drugs whose metabolites play a role in their efficacy and clinical interpretation also need to be determined by chromatography, which analyses multiple components simultaneously. Immunoassays are often not selective enough to distinguish between parent drug and metabolite, and interferences can adversely affect results for some drugs. Another difficulty facing clinical laboratories is that more accurate quantitation and detection requirements must be satisfied owing to lower dosages being administered. The proliferation of new drugs also increases the potential for concomitant administration. When the issue of cost is considered, in addition to the drawbacks listed above for immunoassays, chromatographic techniques can become quite attractive. Most often for clinical bioanalysis, detection methods involve ultraviolet or fluorescence detection coupled with liquid chromatographic separation.

Antidepressants

Tricyclic and newer antidepressant drugs are one of the most frequently monitored classes of therapeutic drugs in the clinical setting. Drug concentrations are monitored in patients for compliance and to ensure that therapeutic blood levels are reached. Also, patients sometimes take multiple antidepressant drugs, often from different physicians, which can be determined from a LC analysis. Immunoassays frequently cross-react with these drugs (e.g., imipramine, amitriptyline, desipramine and fluoxetine) and their metabolites. SPE has been used in some immunoassay kits to measure specifically one tricyclic drug. Overall, LC is advantageous because of its ability to monitor simultaneously multiple drugs and to resolve potential interferences from concomitantly administered drugs.

Solid-phase extraction methods for antidepressant drugs abound in the literature. These drugs are basic and can be adsorbed to reversed-phase sorbents such as C18 and C8 by both reversed-phase attraction and secondary interactions via cationic adsorption to silanols on the silica surface. Polar sorbents such as cyanopropyl, in which the cationic adsorption be-

comes primary, have also been used successfully. Methods for these drugs typically involve a solvent exchange of organic eluent for aqueous/organic mobile phase. Evaporative losses are always a concern with this step, but can be avoided by use of SPE discs, in which elution is accomplished with a small volume of mobile phase solution.

Corticosteroids

The measurement of steroids (prednisone, cortisone, prednisolone, cortisol, corticosterone, methylprednisolone) in blood is often inaccurate owing to interference from sample matrix and cross-reactivity with chemically similar steroids. For example, antiserum for cortisol is nonspecific and cannot differentiate between cortisol, its metabolites and therapeutically administered steroids. Again, SPE is a preferred technique for drug sample preparation. An efficient method has been reported using C8 sorbent discs, which allows for elution in mobile phase compatible solution for direct injection, eliminating the need for a tedious dry-down and reconstitution step. Steroids are released from proteins by incubation at room temperature with a HCl solution. Neutralization is accomplished by addition of a sodium borate solution. Following centrifugation, the supernatant is loaded onto conditioned C8 discs. A dilute methanol-water solution acts as an efficient wash to remove adsorbed proteins. Elution is performed with acetonitrile, followed by water. The resulting mixture is compatible with mobile phase for direct injection.

Cyclosporin

Cyclosporin, an immunosuppressant drug, has many metabolites and is commonly monitored for drug concentrations in the blood of patients who have received an organ transplant. Monoclonal antibody-based immunoassays are in use for this assay, as well as LC methods. Technology for immunoassay detection is constantly being improved, and the tests in use now are reliable. However, LC methods also function quite well, and the issue of antibody versus LC method often rests with cost analysis for a clinic. LC methods rely on SPE using whole blood and, when coupled with automation, can be quite cost effective. An advantage of LC is that it can simultaneously measure several metabolites.

The extraction procedures for cyclosporin are commonly reversed phase. Note that whole blood is preferred to avoid temperature-dependent cyclosporin redistribution. Mixing with acetonitrile-water haemolyses blood, and aliquots of the supernatant are loaded onto conditioned extraction columns. Wash steps may involve a weak concentration of

acetonitrile in water and elution is achieved with methanol or ethanol, or with an alcohol–water solution.

Antiepileptics

Plasma concentrations of antiepileptic drugs are often monitored during therapy, since a therapeutic range has been well defined. These drugs include phenytoin and carbamazepine and their metabolites, phenobarbital and newer agents such as lamotrigine. Solid-phase extraction is commonly performed using reversed-phase sorbents such as C8 and C18. The wash is performed with water, since the more hydrophilic drug lamotrigine is removed from the sorbent bed at low organic concentrations in water. Elution is efficiently accomplished with acetonitrile. Again, the use of the disc SPE formats can allow elution in volumes small enough to eliminate the evaporation step; a small elution volume of acetonitrile is mixed with water and the resulting solution is injected directly onto the liquid chromatograph.

Pharmaceutical Drug Discovery and Development

The discovery and development of new drug entities can be a perplexing task for analytical chemists. Drug molecules that demonstrate activity in receptor assays may exhibit structural characteristics that make them poor candidates for absorption *in vivo*, and other times they may be so rapidly metabolized as to limit their duration of activity in the body. Drugs may be difficult to separate on chromatographic columns, or be so labile that analytical techniques become a challenge. Once these challenges are overcome, the determination of drug concentrations in blood and urine yields the data used to understand the time course of drug action, or pharmacokinetics, in animals and man. Modern requirements for bioanalytical assays include specificity to determine parent drug from metabolites, sensitivity to detect concentrations of ng mL^{-1} and often lower, and speed.

The mainstay for detection following chromatographic separation was formerly ultraviolet or fluorescent detection. These techniques have served the analytical needs well over the years, but newer analytical instrumentation, namely the maturing of MS interfaces to LC, has allowed analytical chemists to use a more powerful detection technique for their routine analyses. The development of more potent drugs has also placed greater emphasis on the determination of lower concentrations of drugs, down to the pg mL^{-1} range. The answer to the analytical need for greater sensitivity, specificity and speed has been LC coupled with tandem mass-spectrometry (LC/MS/MS).

An application illustrating efficient sample preparation required prior to LC/MS/MS analysis is the determination of leukotriene LTE_4 in urine. Leukotrienes are biologically important molecules derived from arachidonic acid by the action of the enzyme 5-lipoxygenase. LTE_4 is difficult to analyse because it is unstable under a variety of conditions. The unique capabilities of MS have yielded detailed structural and metabolic information about these compounds. The extraction of LTE_4 from 5 mL human urine is accomplished by pH adjustment to 4.5 before loading onto a conditioned C18 SPE column or disc. A wash of 5% formic acid is used, followed by elution with a small volume of methanol. The eluate is evaporated and then reconstituted in mobile phase for analysis by LC/MS/MS. This extraction method is simple, yet selective for LTE_4 in human urine. Concentration range tested was 50 pg mL^{-1} to 10 ng mL^{-1} .

A recent advance in improving the throughput of drug development, made possible by LC/MS/MS techniques, is the simultaneous determination of mixtures of drug candidates in single analytical samples as a means to select optimal target drugs. In this case, animals are dosed with several test compounds at once; pooled plasma from multiple animals dosed with single compounds also has been shown. The specificity and sensitivity of the MS detection techniques now available have made this advancement possible. The data generated by this approach have been reported to yield meaningful pharmacokinetic data.

High Throughput Applications of SPE in Bioanalysis

The introduction and utilization of liquid chromatography interfaced with tandem MS techniques has resulted in a dramatic change in sample preparation techniques for drug bioanalysis. The speed of LC/MS/MS, in which run times are typically 1–3 min, allows more samples to be analysed per unit time than traditional HPLC analysis techniques, which require about 10–30 min per sample. The ability of the instrumentation to analyse samples faster than ever before, combined with the emergence of combinatorial chemistry techniques for drug discovery, have put more drugs into the drug development pipeline. The greater number of drugs under evaluation places increased demands on the resources available for pharmacokinetic drug metabolism support. As a result, sample preparation has become the rate-limiting step in achieving higher throughput in bioanalysis.

The pharmaceutical industry has responded to the challenge of higher throughput sample preparation by using a recent advance, SPE in a 96-well microtitre plate format. This technique utilizes single blocks or

plates that have 96 wells containing discs or packed beds of sorbent particles arranged in an 8-row \times 12-column rectangular matrix. Although the plates can be processed manually, instrumentation is preferred for processing liquids through the SPE plates. The advent of high throughput sample preparation formats, in combination with the specificity, sensitivity and speed of LC/MS/MS analytical techniques, have created a superior combination for the analytical chemist to meet the demands for faster sample processing and data generation to support the drug development process.

Conclusion

The future of drug bioanalysis using SPE is promising as more and more laboratories increase the usage of LC/MS/MS instrumentation and justify the need for high throughput SPE. LC/MS/MS instrumentation is now common in pharmaceutical laboratories and clinical laboratories are slowly beginning to demonstrate utility for mass spectrometry for certain drug classes, e.g. tacrolimus (FK506, an immunosuppressant). The 96-well plate format is finding its way into many bioanalytical applications; when coupled with automation, there is currently no faster sample preparation method. Individual SPE cartridges will continue to have a role in sample preparation, but 96-well plates will proliferate in pharmaceutical applications. More bioanalytical applications will adopt smaller sorbent mass products, as the productivity gains from reduced solvent volume are realized, especially using automation. As the sorbent mass in plates decreases, the number of applications that demonstrate elimination of the evaporation step by using small elution volumes of mobile phase compatible solution for direct injection will increase.

Introduction

The term 'biogenic amine' was proposed by Guggenheim in 1940 in order to define the low-molecular-

weight organic bases, produced by the decarboxylation of amino acids, that possess biological activity. Biogenic amines are receiving increasing interest because they are often present in foods, such as cheese, meat, and fish where they are used as a useful indicator of spoilage and markers of food quality. They occur naturally in the central nervous system, where they play an important role as neurotransmitters. Their presence in metabolic pathways in health and disease has been studied because of their biological activity as reported by Parvez *et al.*, and they are

reported to be responsible for diseases related to their biological activity.

Muskiet *et al.* investigated a comparison of the popular high performance liquid chromatographic (HPLC) methods, whose chief advantage is a reduced sample pre-treatment, and other chromatographic techniques, such as gas chromatography, for the separation and determination of biogenic amines. In chromatographic methods, two main steps are neces-

sary: (a) the separation of amines from the matrix and (b) their determination. Pre-column derivatization is very often required for selectivity and sensitivity enhancement.

Sample Preparation

The first step is the most critical in terms of obtaining an adequate recovery for amines, because of the

Figure 1 Dual chromatograms of amines as *N(O)*-isobOC, *O*-TBDMS derivatives separated on DB-5 and DB-17 (both 30 m \times 0.25 mm I.D., 0.11 μ m film thickness) dual-capillary column system. GC conditions are described in the text. Peaks: 1 = ethyl-methylamine; 2 = *tert*-butylamine; 3 = diethylamine; 4 = *sec*-butylamine; 5 = isobutylamine; 6 = diisopropylamine; 7 = *n*-butylamine; 8 = dipropylamine; 9 = pyrrolidine; 10 = isoamylamine; 11 = morpholine; 12 = piperidine; 13 = *n*-amylamine; 14 = diisobutylamine; 15 = thiazolidine; 16 = *n*-hexylamine; 17 = dibutylamine; 18 = cyclohexylamine; 19 = *n*-heptylamine; 20 = diphenylamine; 21 = *o*-toluidine; 22 = benzylamine; 23 = *n*-octylamine; 24 = *m*-toluidine; 25 = *p*-toluidine; 26 = β -phenethylamine; 27 = dihexylamine; 28 = *n*-decylamine; 29 = 2,4-dichlorobenzylamine; 30 = dicyclohexylamine; 31 = 1,3-diaminopropane; 32 = 3,4-dichlorobenzylamine; 33 = β -hydroxyphenethylamine; 34 = norephedrine; 35 = ephedrine; 36 = putrescine; 37 = 3,4-dimethoxyphenethylamine; 38 = diethanolamine-1; 39 = dibenzylamine; 40 = cadaverine; 41 = diethanolamine-2; 42 = histamine; 43 = 1,6-diaminohexane; 44 = tryptamine; 45 = 1,7-diaminoheptane; 46 = tyramine; 47 = 3-methoxytyramine; 48 = 5-methoxytryptamine; 49 = synephrine; 50 = octopamine; 51 = metanephrine; 52 = 3,4-dihydroxybenzylamine; 53 = normetanephrine; 54 = dopamine; 55 = spermidine; 56 = serotonin; 57 = epinephrine; 58 = norepinephrine. (Reproduced with permission from Kim KR *et al.* (1997).)

complexity of the matrices usually considered. All matrices pose different problems depending on their complexity so many clean-up techniques have been proposed making use of different extraction procedures, i.e. liquid-liquid, solid-phase extraction (SPE), etc. and a variety of solvents (perchloric, trichloroacetic, and hydrochloric acids and/or both polar and non-polar organic solvents).

In the second step, account must first be taken of the amine pre-column derivatization; this is often, if not always, necessary for enhancing the analyte response and selectivity. The other aim of pre-column derivatization is to obtain derivatives, which are both volatile and sufficiently stable for subsequent analyses. Gas chromatographic analysis of the amines requires one or more appropriate derivatization procedures to block active protons in amino and other polar groups and acylation, silylation, benzoylation, sulfonylation, phosphorylation and alkylloxycarbonylation have been used. Baker *et al.* have given an example of a complete study of the derivatization process in biogenic amines determination.

Chromatography

Separations are mostly performed on capillary columns whose length ranges from 15 to 30 m. The silica capillary columns are coated with different film thickness of methylsiloxane, methylphenylsiloxane, or cyanopropylphenylsiloxane polymers or polyethylene glycols. Only a few examples in the past reported the use of packed columns. Both isothermal and programmed temperature conditions are used.

Detection

Among the different detectors used in gas chromatography for biogenic amine analysis, the four detectors most commonly used are: flame ionization detector (FID), electron-capture detector (ECD), nitrogen-phosphorus detector (NPD) and mass spectrometry (MS).

Flame Ionization Detector (FID)

Some biogenic amines such as aliphatic mono-, di- and polyamines do not exhibit structural features that

permit their specific detection, in this case a non-specific detector such as flame ionization (FID) can be used, but the lack of sensitivity and/or selectivity may require the use of other detectors coupled with FID as shown in Table 1.

Bock and Waser acylated, via a single-step reaction, some biogenic amines for their specific and quantitative gas chromatographic assay. The retention times were found to be inversely proportional to their molecular weights and also to the number of the pentafluorobenzoyl groups. FID and ECD detector responses were compared; FID was selected for nanogram range and ECD for picogram range determinations, in order to optimize linearity and accuracy. The structure of the derivatives was confirmed by GC-MS technique.

Yamamoto *et al.* proposed a routine method for the determination of polyamines as their *N*-ethyloxycarbonyl derivatives. The sample preparation is simple and reproducible and the derivatives are stable. Also in this case, the identity of the derivatives was confirmed by GC-MS technique.

Muskiet *et al.* prepared extracts of acid-hydrolysed biological fluids by pre-purification with silica gel to give recoveries of better than 90%. The isolated compounds were derivatized and simultaneously determined by a capillary gas chromatographic method. FID and NPD detector responses were compared showing that NPD is both more selective and sensitive than FID.

Laleye *et al.* developed trifluoroacetylation for quantifying biogenic amines on a microgram scale in foods.

One of the most recent and notable applications of FID detector is the determination of 57 amines described in the paper of Kim *et al.* In their work they demonstrated the wide applicability of the FID supported by the simultaneous use of two capillary columns of different polarity, such as DB-5 and DB-17 for resolving all the considered amines, as shown in Figure 1. The proposed method is based on two-phase isobutyloxycarbonylation with a pH shift. The resulting derivatives are separated by SPE and the remaining hydroxyl groups are derivatized for dual capillary column gas chromatographic analysis. Response is linear in the 0.2–12-ppm range.

Electron-Capture Detector ECD

Examples of the use of the electron-capture detection (ECD) are given in Table 2.

Staruskiewicz and Bond developed a procedure for the quantitative determination of putrescine and cadaverine in foods. The amines were extracted with methanol and a dry residue of their hydrochloride salts was prepared. The salts were derivatized and both the reagent excess and reaction by-products were removed by means of an alumina column, minimizing in this way the solvent fronts and interfering extraneous peaks, some of which adversely affected the ECD response. The recovery of diamines was within the range 97 to 102%. Gas chromatographic separation was performed and the retention time for the derivatives of putrescine and cadaverine was found to be 4.3 and 5.7 min, respectively. When

Table 2 GC of biogenic amines with ECD detection

Analyte	Chromatographic column	Carrier, type and flow rate	Injector temperature and program	Matrix	Sample treatment	Reference
Histamine, <i>tele</i> -methylhistamine, <i>m</i> -, <i>p</i> -tyramine, 3-methoxytyramine, putrescine, cadaverine, tryptamine, spermine, spermidine, 2-phenylethylamine, 5-hydroxytryptamine	Fused silica capillary SE-54, length 15 m, i.d. 0.25 mm	He, 2 mL min ⁻¹	250°C, 105°C → 25°C min ⁻¹ → 240°C	Foods	Liquid-liquid extraction, derivatization with pentafluorobenzoyl chloride-benzene-acetonitrile	Baker <i>et al.</i> (1987)
Cadaverine, putrescine, spermine, spermidine	3% OV-17 on Chromosorb W HP packing length 1.5 m, i.d. 3 mm	He, 60 mL min ⁻¹	120°C → 15°C min ⁻¹ → 280°C	Biological fluids	SPE purification, derivatization with heptafluorobutyric anhydride	Fujihara <i>et al.</i> (1983)
Cadaverine, putrescine	3% OV-225 on Gas Chrom Q 100-120 mesh packing, length 1.8 m, i.d. 2 mm	He, 28 mL min ⁻¹	200°C, 180°C isothermal	Foods	Liquid-liquid extraction, derivatization with pentafluoropropionic anhydride, SPE purification	Staruszkiewicz and Bond (1981)

Figure 2 Gas chromatogram of extracts of bioactive amines from (top) cheese sample and (bottom) a solution of authentic standards. Extraction and derivatization were as described in the text. Derivatives of 2-phenylethylamine (A); 2-(4-chlorophenyl)ethylamine, internal standard (B); *tele*-methylhistamine (C); histamine (D); putrescine (E); tryptamine (F); cadaverine (G); *m*-tyramine (H); *p*-tyramine (I); 3-methoxytyramine (J); 5-hydroxytryptamine (K); spermidine (L); and spermine (M). Attenuation changes were programmed in to ensure that all peaks remained on scale for the purpose of illustration. (Reproduced with permission from Baker GB *et al.* (1987).)

compared to a nitrogen-specific detector, the ECD had greater sensitivity. Less than 1 ppm of diamine in the food can be quantitated with a coefficient of variation lower than 3.0%.

Fujiyama *et al.* developed a sensitive and selective method for the estimation of polyamines in biological fluids after their separation from other compounds and derivatization. These derivatives are well resolved within 15 min with detection limit of 0.1 pmol for putrescine and cadaverine and 0.02 pmol for spermine and spermidine.

Baker *et al.* proposed a method based on extractive derivatization of the amines with a perfluoroacylating agent under basic aqueous conditions. Polyamine recovery was virtually quantitative, whilst for the other amines the recoveries ranged from 70 to 85%. Derivatives showed good chromatographic properties and ECD was used for enhancing sensitivity of biogenic amines in food samples. The derivative structures

were confirmed by GC-MS. The detection limits (peak/noise ratio = 2) of the different types ranged between 5 and 20 pg on-column and calibration curves were linear over two orders of magnitude.

A typical chromatogram obtained with this technique is shown in Figure 2, that is relative to the determination of perfluoroacetyl derivatives in foods. The method of Baker *et al.* resulted in a reference paper for all later authors using the ECD.

Nitrogen-Phosphorus Detector (NPD)

Another very specific detector for amines is the nitrogen-phosphorus detector (NPD). The most recent papers relative to the use of this detector for biogenic amine determination are reported in Table 3.

One of the first comparisons between FID and another detector (NPD) appeared in the paper of Muskiet *et al.* These authors prepared extracts of acid-hydrolysed biological fluids by pre-purification with silica gel. The isolated compounds were derivatized and simultaneously determined by capillary gas chromatography with nitrogen-phosphorus detection. Their comparison between typical chromatograms obtained with FID and NPD is shown by an example in Figure 3.

Perez-Martin *et al.* also compared FID and NPD results, but contrary to Muskiet *et al.* they considered both detector responses as equivalent. These authors treated seafoods with trichloroacetic acid and then extracted the resulting solution with benzene under highly basic conditions. Retention times are 1.03 min for dimethylamine and 1.35 min for trimethylamine.

Hessels *et al.* developed a capillary gas chromatographic method with NPD for the determination of the *N'*-acetylspermidine catabolite in biological fluids and compared it with the GC-MS method of Van den Berg *et al.*, shown in Table 4. The results were within a relative standard deviation of 3%.

One of the most recent applications of NPD for polyamines profiling is the work of Dorhout *et al.* that used capillary gas chromatography with NPD for the determination of polyamines, *N*-acetylated polyamines and the polyamine analogues *N'*,*N''*-bis(ethyl)norspermine and 1,19-bis(ethylamino)-5,10,15-triazanonadecane in biological samples. The suggested method provided for the use of four internal standards and pre-purification steps comprising deproteinization and isolation on silica at pH 9.0 with 70–90% recoveries depending on polyamine type. The precision is better than 7%, while the detection limits (peak/noise ratio = 2) of the different components ranged from 0.4 to 0.7 pmol. Figure 4 shows a typical chromatogram obtained with the method described in the Dorhout work.

Table 3 GC of biogenic amines with NPD detection

Analyte	Chromatographic column	Carrier, type and flow rate	Injector temperature and program	Matrix	Sample treatment	Reference
Putrescine, cadaverine, spermine, spermidine, 1,3-diaminopropane	Fused silica capillary methyl silicone phase, length 37.5 m, i.d. 0.20 mm, film thickness 0.11 μm	He, 0.6 mL min^{-1}	260°C, 120°C \rightarrow 5°C min^{-1} \rightarrow 260°C \rightarrow 2°C min^{-1} \rightarrow 280°C	Biological tissues	Deproteinization, SPE purification and derivatization with heptafluorobutyric anhydride	Dorhout <i>et al.</i> (1997)
Polyamines, <i>N</i> -acetylspermidine	Fused silica capillary HP 17, length 25 m, i.d. 0.20 mm, film thickness 0.17 μm		260°C, 180°C \rightarrow 3°C min^{-1} \rightarrow 270°C	Biological fluids	Alkalization, liquid-liquid extraction and SPE purification	Hessels <i>et al.</i> (1991)
Trimethylamine, dimethylamine	4% Carbowax 20M + 0.8% KOH on Carbowax B and Chromosorb 103 packing, length 1.8 m, i.d. 2 mm	N ₂ , 25 mL min^{-1}	250°C, 115°C isothermal	Seafoods	Liquid-liquid extraction	Perez-Martin <i>et al.</i> (1987)
Cadaverine, 1,3-diaminopropane, putrescine, isoputrescine, putrescine, spermine, spermidine	Fused silica capillary cross-linked methyl silicone and siloxane deactivated, length 35 m, i.d. 0.20 mm, film thickness 0.11 μm	He, 0.5 mL min^{-1}	300°C, 120°C \rightarrow 7°C min^{-1} \rightarrow 260°C	Biological fluids	SPE purification, derivatization with heptafluorobutyric anhydride	Muskiet <i>et al.</i> (1984)

Mass Spectrometry (MS)

The actual trend in biogenic amine gas chromatographic analysis is to establish a complete profile of all the important amines by using a single method, thus the widest used detector is mass spectrometry (MS) (Table 4). This technique was formerly used in conjunction with other detectors for confirmation purposes only.

The advantage of MS over other detection systems is based on the possibility of identifying compounds with a high degree of specificity. This can be realized using high resolution capillary gas chromatography combined with the monitoring of characteristic ions in the mass spectrum of a compound (GC-MS). GC-MS can afford characteristic ratios of ion intensities or the m/z value of a particular ion. These parameters may be changed in a predictable manner by derivatization processes in order to provide additional proof of identity.

Duncan *et al.* compared the results obtained using both HPLC with electrochemical detection and GC-MS in the single-ion monitoring mode (SIM) when applied to dopamine and norepinephrine (noradrenaline) determination, after a single-step alumina extraction, in a selection of food and beverage

samples. The results provided an opportunity for qualitative and quantitative comparison of these two techniques and discussion of their respective merits and limitations.

The specificity associated with SIM is responsible for a significant reduction in the complexity of data obtained when using a GC-MS system. The use of appropriate deuterated internal standards eliminates the influence of the original sample matrix, minimizing sample pre-treatment, and allows precise multi-component quantitation at low levels.

Davis *et al.* preferred to use GC-MS in the multiple-ion detection mode (MID) after derivatization with two different reagent systems and precipitation of protein with sulfosalicylic acid prior to extraction, in order to analyse a large number of biogenic amines and their metabolites in a single run.

Van den Berg *et al.* described the identification of a metabolite of spermidine by GC-MS in biological fluids of normal healthy humans and cancer patients. The quantification was based on stable isotope dilution mass fragmentography monitored at m/z 185 and 188.

Fujihara *et al.* measured putrescine metabolism in biological fluids. Putrescine was decomposed by oxidative deamination to form ammonia that was

determined by GC-MS. Its quantification was based on mass fragmentography synchronously monitored at m/z 195, 211 and 212. The method is inferior to isotope mass spectrometry, but its speed, reproducibility (better than 0.5%) and sensitivity are superior.

Shafi *et al.* applied GC-MS in the negative ion chemical ionization mode (NICI) for the determination of biogenic amines. After derivatizing the amines and separating them by solvent extraction, they hydro-

lysed the phenolic esters and converted the free hydroxyl groups to trimethylsilyl esters and analysed these derivatives by GC-MS-NICI. The molecular ion of these derivatives (together with the isotope peaks) carried more than 60% of the ion current, which made the method highly specific and gave a potential limit of detection below the picogram level.

This technique has the advantage that the silylating reagent may be changed in order to shift both the m/z

Table 4 GC-MS of biogenic amines

Analyte	Chromatographic column	Carrier, type and flow rate	Injector temperature and program	Matrix	Sample treatment	Reference
<i>p</i> -Tyramine, <i>p</i> -octopamine, <i>p</i> -synephrine, dopamine, noradrenaline, adrenaline, 5-hydroxytryptamine	Fused silica capillary HP 1, length 12.5 or, 25 m, i.d. 0.20 mm, film thickness 0.2 μ m	He, 40 mL min ⁻¹	250°C, 100°C → 10°C min ⁻¹ → 300°C	Biological tissues	Liquid-liquid extraction and derivatization with 5-ditrifluoromethylbenzoyl chloride and isopropyl dimethylsilyl- <i>N</i> -methyltrifluoroacetamide	Shafi (1995)

value of the molecular ion and the retention time of the derivative to ensure that its identification is unequivocal. In the same laboratories MacFarlane *et al.* used a similar procedure, but they state that the ion current was generally carried by four or five large ions.

Musshoff *et al.* derivatized the compounds formed by reaction of formaldehyde with biogenic amines in biological fluids in order to avoid the simultaneous formation of these compounds via condensation. These derivatization products are stable and can be well purified from most of the interfering matrix compounds by liquid-liquid and solid-phase extraction. They have good GC-MS properties, therefore the retention times, together with the diagnostic mass fragments (at least three) and the specific ion ratios, can be used for separation and identification.

Shafi summarized the use of different derivatizing agents, whose scope was shifting both the m/z value and the retention time in order to ensure the unequivocal identification of amines (Figure 5). In each case, the principal ion in the mass spectrum was the molecular ion, which carried almost all of the ion current under negative ion chemical ionization conditions; the sensitivity of this method of derivatization was 1 pg of biogenic amine on-column.

The possibility of easy determination of biogenic amines by other chromatographic techniques, such as HPLC, has reduced the interest in updating the existing gas chromatographic methods.

BIOLOGICAL SYSTEMS: ION EXCHANGE

R. J. P. Williams, Imperial College,
London, UK

Copyright © 2000 Academic Press

There are two very different processes which are described under the heading of ion exchange within biological systems. The first is exchange in an aqueous environment of two different ions, M_A and M_B , held by a molecule in free solution, or in a precipitate, or on a membrane surface:

Here, M is a metal cation and X is an anion, often an organic molecule which can be as large as a protein or DNA. Exchange of anions is also possible, as in the equilibrium:

Both eqns [1] and [2] have been written for exchanging ions of equal charge type n . This is not a necessary condition, so we can also consider:

Again, the charge balance shown so far in the equations is not essential, so we must also examine the situation of electrogenic exchange:

where charge distribution is associated with MX changes. Before considering the second way in which ion exchange can occur across a membrane, we give one or two examples of ion exchange to and from a bound condition in a single aqueous solution.

Exchange of Major Cations and Anions in Cells

The major small cations and anions in cells which undergo ready exchange are shown in Table 1. They may associate with one another in rapid exchange or

bind to surfaces of proteins, other polymers, precipitates or membranes and exchange rapidly or slowly.

Consider a magnesium protein such as Mg^{2+} parvalbumin, where parvalbumin is a common anionic metal-ion-binding protein in muscle cells. When the protein, which is magnesium bound in the cell, is exposed to calcium, the reaction of exchange occurs: Ca^{2+} parvalbumin is formed and Mg^{2+} is freed. If the initial protein complex had been Na^{+} parvalbumin, then replacement by Ca^{2+} would have been electrogenic, unless of course two Na^{+} ions had been bound originally.

A second example of exchange on the surface of a polymer is provided by polynucleotides such as RNA and DNA. These polymers have anionic phosphate backbones and their negative charges are balanced, not entirely randomly, by exchanging cations, including particularly K^{+} , Mg^{2+} and ammonium derivatives. The positive charge, like the negative charge, in an exchanging system can also be carried on a large molecule and in biology there are many polyamines and positively charged proteins, such as histones, which bind DNA. They can bind and exchange anions such as HPO_4^{2-} and SO_4^{2-} .

A further example of biological metal ion exchange in one aqueous solution now involving a solid precipitate is the case of bone, which we can write as $(Ca^{2+})_2(OH^{-})PO_4^{3-}$ for simplicity. Bone scavenges many other cations by exchange and contains considerable amounts of Mg^{2+} and even Al^{3+} in place of Ca^{2+} . Bone also exchanges Ca^{2+} for protons (H^{+}). This mineral is additionally an anion-exchanging solid in which some OH^{-} is replaced by F^{-} (a process used in the protection of teeth). To some extent, a pair of $OH^{-} + PO_4^{3-}$ can be replaced by $2CO_3^{2-}$ anions. Notice that exchange can be electrogenic when charge is left on the surface of the bone mineral.

The last example of this relatively simple exchange is at the surface of membranes. All biological membranes carry negative charge due to covalently bound phosphate or carboxylate groups. Since the charges are quite close-packed, the membranes have a considerable affinity for cations and all membranes have associated K^{+} and Mg^{2+} (mainly internally) and Na^{+} and Ca^{2+} (mainly externally) associated with their surfaces. The outermost coats of cell walls in Gram-negative bacteria are also anionic and are stabilized by exchangeable cation, often Ca^{2+} , incorporation.

Table 1 Major small cations and anions of cells

Cation	Anion
Na^+ largely rejected	Cl^- largely rejected
K^+ cytoplasmic	HPO_4^{2-} cytoplasmic
Mg^{2+} cytoplasmic	SO_4^{2-} cytoplasmic
Ca^{2+} rejected (vesicular)	HCO_3^- balanced
RNH_3^+ cytoplasmic	RCO_2^- cytoplasmic
	ROPO_3^{2-} cytoplasmic

H^+ (pH 7); OH^- (pH 7).

Exchange of Trace Elements

Major exchange of trace elements (Table 2) occurs from many carrier or buffer proteins. For example, iron is carried in the blood stream of higher animals by the protein transferrin in the form of Fe^{3+} , in co-association with the carbonate anion, CO_3^{2-} . The uptake into the cell involves the transfer of the whole protein to a vesicle, the lysozyme, which is much more acidic than blood. There the protein loses both iron and CO_3^{2-} , which are exchanged for bound protons. The iron is processed further into the cell as Fe^{2+} , only to be reoxidized in a precipitate inside a protein matrix, ferritin, where it is stored as $\text{Fe}(\text{OH})_3$. From this small particle, iron exchanges into the cytoplasm, to give a great variety of compounds (see Figure 1) for the case of bacteria.

A second example of cytoplasmic ion exchange of trace elements involves both copper and zinc bound to sulfur-containing proteins. The proteins release copper or zinc (M) to the cytoplasm in equilibrium with free hydrogen ions:

where Pr is a protein such as metallothionein. This equilibration ensures constant levels of Zn^{2+} and Cu^+ in the cytoplasm.

Trace anions are also carried in the blood stream by special proteins and are then transported into cells. The proteins which transfer SO_4^{2-} , SeO_4^{2-} and MoO_4^{2-} are known to be similar to transferrin.

Table 2 Trace cations and anions of cells

Cation	Anion
Mn^{2+} vesicular	SeO_4^{2-} cytoplasmic
$\text{Fe}^{2+}/\text{Fe}^{3+}$ cytoplasmic (precipitate)	MoO_4^{2-} cytoplasmic
Co^{2+} cytoplasmic	I^- cytoplasmic
Ni^{2+} vesicular	NO_3^- cytoplasmic
Cu^{2+} rejected	
Zn^{2+} cytoplasmic	

Many of the ions are held in complexes with organic agents.

Figure 1 An outlined scheme of the variety of ion exchange reactions in the uptake of iron. Iron is captured as Fe^{3+} outside the cell by a small organic molecule, ferroxamine (X). FeX is passed through membranes (TON B) using energy, and is then exchanged in a variety of paths. Some involve proteins, P; some enzymes catalyse for example the citrate cycle. Some iron is exchanged into new small organic molecules, porphyrins, to make new enzymes. Finally, much is stored in a bound small particle of $\text{Fe}(\text{OH})_3$, called ferritin.

Ion Exchange across Membranes

A different form of ion exchange is that which occurs across a membrane separating two aqueous phases (Figure 2). Once again, the simplest exchange is of two ions, cations such as Na^+/K^+ , $\text{Mg}^{2+}/\text{Ca}^{2+}$ or of anions such as OH^-/Cl^- , where there is equal charge maintenance but change of concentration on both sides of the membrane. There are other possibilities than exchange of equally charged ions, such as the exchange of $2\text{Na}^+/\text{Ca}^{2+}$ or $2\text{Cl}^-/\text{HPO}_4^{2-}$, when only concentration changes are again involved on exchange. The further possibility is that the exchange process is electrogenic, when charge differences are built up across a membrane. Simple examples are the exchanges of $\text{H}^+/\text{Ca}^{2+}$ or $\text{OH}^-/\text{HPO}_4^{2-}$.

In the case of electrogenic exchange, an electrical potential develops across the membrane. Such potentials exist across most membranes of all cells but to different degrees. The development of such ion exchange potentials has led to the successive evolution from simple cells to nerves and then to the brain. In these cells Na^+/K^+ exchange carries the electrolytic current.

Examples of exchange of ions across membranes are numerous in biological systems. One of the best known is the $2\text{Na}^+/\text{Ca}^{2+}$ exchange in many slow

Figure 2 The distribution of the major anions, Cl^- and RPO_4^{2-} and cations, Na^+ , K^+ , Ca^{2+} and Mg^{2+} across a biological cell membrane. Filled circles, charged (negative) phospholipids; open circles, uncharged lipids.

muscle cells. This exchange occurs after muscle action is triggered by the invasion of Ca^{2+} and is used to restore the resting state of a muscle such as that of the heart. An example of electrogenic exchange is found in the nerve when 2K^+ ions enter the cell in exchange for 3Na^+ , thus creating a membrane potential (Figure 3). However, this process costs energy and was a later development in evolution. We turn to the energetics of such exchange processes below.

Figure 3 The adenosine triphosphate (ATP) pump in mammalian cells. It exchanges 3Na^+ for 2K^+ and is electrogenic. The concentration of ions inside and outside human cells is shown below.

The Natural Environment and Ion Exchange

To appreciate the value of ion exchange in biological systems, we must look at the environment of cells and the nature of cellular organic chemicals. The major fluids surrounding cells are the sea, fresh water and artificially maintained body fluids for multicellular species such as humans living in air. All of these fluids are aqueous electrolyte solutions containing elements as ions, as shown in Figure 3. The composition of the sea is given in Figure 4. The major feature of the internal cellular solution, that is, the solution protected by the cell's membrane, called the cytoplasm, is that it contains many organic molecules and anions. Both the environmental fluids and the cytoplasm have an osmotic pressure which, unless counter measures are taken to exclude many of the ions of the environment, will be greater for the cytoplasm due to the organic molecules present there. Hence all cells are in danger of bursting through osmotic stress. Due to the anionic nature of the organic molecules in the cell and the fact that the membranes themselves are also anionic due to the phospholipid head groups, they are also in danger of breakdown due to internal electrostatic repulsion between the anions. Various ways of overcoming these problems have been observed in different biological cells and they frequently involve ion-exchange.

Osmotic stress can be overcome by protecting the outer membrane by a cell wall. This wall, built from anionic organic cross-linked polymers, is commonly found in bacteria and plant cells. The anionic wall is exposed to the environment and acts as an ion-exchange resin accepting especially Ca^{2+} and Mg^{2+} ions, which considerably strengthen the wall by cross-linking the organic polymers in it. These cations freely exchange with the environment, so that the wall

Figure 4 The concentrations of elements in various ionic forms in the sea. Surfaces of cells exchange ions with all these species but clearly those up to atomic number 20 dominate. However, a biological cell exchanges and picks up more than 20 elements, including molybdate and iodide (from Cox 1995, with permission).

does not have a fixed chemical composition and acts much like an artificial ion exchange resin.

All cells, bacterial, plant and animal, also overcome osmotic stress by the selective admission and rejection of ions of the environment. The major ions of the environment are Na^+ and Cl^- , and in the case of the sea they are quite highly concentrated. Both must be prevented from equilibrating between the environment and the cytoplasm if the cell is not to burst. However, to maintain approximate electrical neutrality there has to be counterions to the anionic organic constituents of the cell. Hence, all cells admit K^+ and Mg^{2+} ions and reject Na^+ and Cl^- ions to a greater or lesser degree (Table 3). Of course, this arrangement of ions across the cell membrane costs energy, so the forced exchange of ions must use an energy source internal to the cell.

Before describing the modes of employing energy in pumping ions across membranes so as to establish

nonequilibrium conditions, we need to observe that cells have to move many substances other than Na^+ , K^+ , Mg^{2+} and Cl^- (Table 3). Firstly, they need to exclude Ca^{2+} , since at the concentration of the environment these ions would precipitate cell anions such as carboxylates and phosphates. Secondly, the cytoplasmic level of anions such as phosphate is too low and that of sulfate is too high in the environment, especially in the sea, so that their cellular concentrations must be controlled. Thirdly, the cell must be able to take in anions (or cations) useful as food for synthesis of organic molecules and these include nitrate, small organic phosphates and carboxylates and ammonium or small amine cations. Fourthly, there are a variety of trace elements in the environment, all of which are required in selected amounts in the cell; for example, cations such as those of iron and manganese and anions such as selenate and molybdate. Finally, we have not mentioned the universal presence

Table 3 Pumped gradients of metals and their complexes

Metal	Inward to cytoplasm	Outward to	Organelle or vesicle
Na^+		Free ion	Outside
Mg^{2+}	Free ion		
H^+	Free ion and many ligands	Free ion and many ligands	Vesicles, outside
K^+	Free ion		
HPO_4^{2-}	Free ion	Several organic phosphates	Mitochondria
Cl^-	Free ion	Free ion	Outside
Fe^{3+}	Ferroxamines, etc.		
	Transferrin	Citrate	Mitochondria
Co^{2+}	Vitamin B_{12}		
Ca^{2+}		Free ion	Reticula, outside

of the proton H^+ which is in constant exchange with many anionic surfaces. Very much of the energy of biological reactions is expended in ion exchange across membranes.

Energized Ion Exchange

There are two major sources of energy open to cells. One is a gradient of protons, H^+ (a pH gradient), developed from the action of light or from the oxidation of organic molecules (Figure 5), while the second comes from the hydrolysis of pyrophosphate bound to nucleotides such as adenosine triphosphate (ATP). The proton gradient can be used in direct ion exchange with other ions, X , across the membrane to accumulate them:

or to develop unfavourable gradients for protection by removing X or M from the cell to the environment:

The first is termed a symport and the second an antiport. In every case, movement across the membrane can be aided by carriers, M or X in the membrane, or by utilizing channels. Channels are controlled, gated pores through membranes.

Figure 5 A simplified picture of the production of a proton gradient and then of ATP by the action of light or oxidation of organic molecules inside a membrane. The gradient or ATP is then connected (X) to aqueous phases when ion (M) exchange across membranes can be driven, indicated by \rightleftharpoons , the symbol for a condenser.

Table 4 Examples of ATP-driven ion exchange pumps in cell membranes

Pump	Function
K^+/Na^+	K^+ moves in; Na^+ moves out. Nerve conduction
H^+/Ca^{2+}	Ca^{2+} moves out. Fast (skeletal) muscle recovery
H^+/M	Trace element input or rejection

The use of ATP is that its hydrolysis energy ($-\Delta G$) can pump ions across membranes:

It is now known that the action of ATP pumps frequently involves ion exchange so that transfer of one cation or anion is coupled to transfer of a second ion in the opposite direction, giving ion exchange while building energized ion gradients. Examples are given in Table 4.

Selectivity of Ion Exchange

The selectivity of ion exchange interactions depends on the relative binding strengths of ions to a site, where the site may be a molecule free in the cytoplasm, a carrier molecule in a membrane, a surface of a membrane or a precipitated phase, or part of a channel or a pump for moving ions across membranes. The affinity for the site can usually be expressed in a very simple form as a binding stability constant, K , for the equilibrium:

where $K = [MX]/[M][X]$.

The concentration of X is here treated in mass action equations and takes a similar form for surface sites or sites in free solution. In the case of surface sites, the equation takes the form of a Langmuir isotherm.

Selectivity of binding depends on the size and charge of an ion in the first instance. It would be expected that small highly charged ions of opposite sign would bind together best, but this expectation is not fully borne out in practice, since competition for a site also depends on constraints due to hydration of the ions:

Since small, highly charged ions are the most strongly hydrated, making for competition between H_2O and

Figure 6 The molecule shown at (A) can bind the monovalent ions selectively because of how it wraps around them (C). The hole in the middle selects the size of the ion, as shown by the binding constants (B). The best binding is for potassium. Such molecules can pick up cations and transfer them across membranes, exchanging the ion for other ions according to binding strengths and concentrations. Many antibiotics are based on such exchange possibilities.

X, there is the possibility of matching ions, M , of different charges and sizes with particular kinds of designed exchange site, X . Controlling factors now for cations, M , are the charge on X and the steric restrictions present in X or induced in MX on binding. Real examples illustrate the point that the binding of cations M to sites X can be in almost any order. The case of the preferred selection of K^+ over the smaller and larger ions Li^+ , Na^+ , Rb^+ and Cs^+ illustrates the point in **Figure 6**. In all cells the K^+ channel virtually excludes Na^+ . Similarly, the Ca^{2+} pump of most cells excludes Mg^{2+} . In both bases the larger ion is preferred due to the size of the cavity and the accepting anion, X .

For trace element metal ions such as those of iron (Fe^{2+} , Fe^{3+}), zinc (Zn^{2+}) or copper (Cu^+ , Cu^{2+}), facts other than charge and size influence selectivity. They are the ability to form covalent bonds depending on the electron affinity of the cation and stereochemical preferences of the metal ions due to their polarizability. Again, examples illustrate these points.

A very important distinction between the bindings of the major metal ions, Na^+ , K^+ , Mg^{2+} and Ca^{2+} and the trace elements, is that the binding units X for the former generally employ organic molecules containing oxygen (O) donor centres only, while for the trace elements the group X may utilize nitrogen (N) or sulfur (S) donors. Examples are given in **Table 5**. Amongst the trace elements the strength of binding follows the general series of divalent M^{2+} ions:

The additional selectivity factor arises due to the stereochemical preferences of these ions.

We can now consider the cytoplasm of a cell as a solution of ion exchange centres, often proteins, which can all bind M but with different affinities.

Together with the fact that the amounts of ions, M , in the cytoplasm varies from $10^{-1} \text{ mol L}^{-1}$ (Na^+ , K^+) to $10^{-17} \text{ mol L}^{-1}$ (Fe^{3+}), this chemical selectivity leads to a virtually complete fixation of the M distribution on different X centres. However, it must not be forgotten that these associations are not permanent and exchange takes place all the time. Many sites will only be occupied preferentially, not specifically, by a given cation. This is particularly important when the environment becomes polluted.

The selective uptake of anions follows similar properties based on size, charge and steric constraints. However, covalent attachment is much less significant than hydrogen bonding. The ability to form hydrogen bonds by anions appears to be related to surface charge density. Thus, F^- and OH^- readily form H bonds when compared with Cl^- , Br^- or SH^- . Once again, the anions exchange quite rapidly with organic surfaces.

Ion Exchange and Cell Compartments

The selectivity of binding to carriers, to channels and channel parts of pumps in membranes leads to

Table 5 Preferred metal/nonmetal ion association

Metal	Preferred nonmetal association
Na^+ , K^+	Low association, preference for O-donor
Mg^{2+} , Ca^{2+}	Moderate association with O-donor anions such as carboxylates and phosphates
Fe^{2+} , Co^{2+}	Strong association with mixture of N- and O-donors
Cu^{2+} , Zn^{2+}	Strong association with S-donor such as thiolates

Exchange is fast for Na^+ , K^+ but progressively slower down the table.

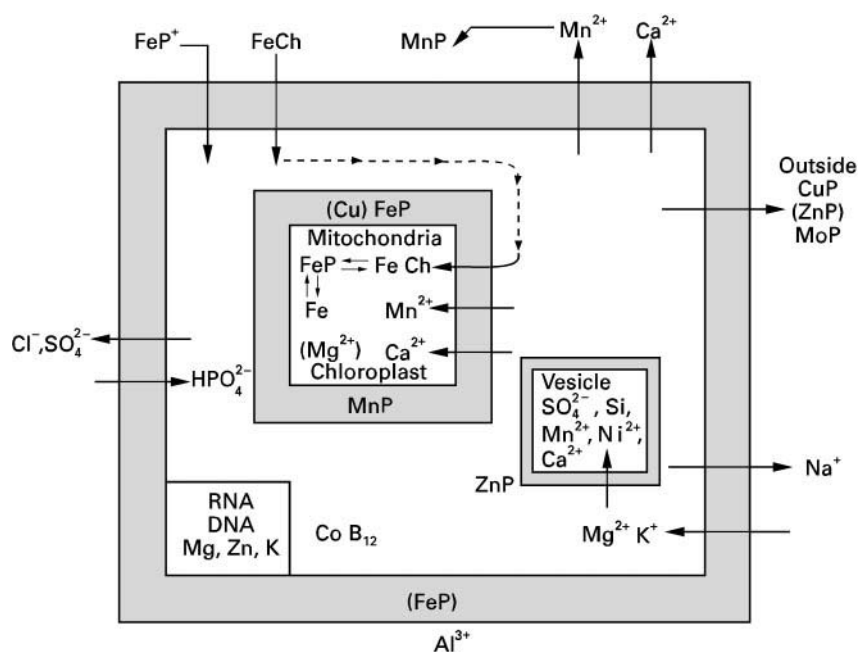

Figure 7 Some of the distributions of elements in eukaryotic cells. Iron is often in membranes, while Cl^- , Ca^{2+} and Na^+ are concentrated away from the cytoplasm; K^+ and Mg^{2+} concentrate inside cells, Mn^{2+} is to be found in vesicles, but copper is more usual outside cells. Zinc is everywhere and cobalt is rare everywhere. Aluminium may be rejected. P, Protein; Ch, chelating agent. Many movements are due to ion exchange.

separate movement of elements in cells and then positions them in particular zones of vesicles. Within these zones, ion exchange of the selected M ions at X occurs, so that selectivity of association is manipulated by the input of energy. Some cell compartments and their selective element contents are shown in Figure 7.

The setting-up of such ion gradients across membranes has great value, not only in that it allows specific reactions to occur in particular parts of space but also that, under stimulus, the ions can be released from their storage sites into the cytoplasm. There is then ion exchange signal. A particularly important example concerns the storage and subsequent release of calcium ions from vesicles into the cytoplasm, causing manifold changes in metabolism and mechanical structure. Simple examples are muscle contraction and hormone release.

We can look upon a mineral phase as a compartment where minerals such as amorphous silica (often in plants), calcium carbonate and calcium hydroxyphosphate are the obvious examples. These precipitates, by exchanging ions, can buffer solutions holding ions in their neighbouring solutions in fixed amounts.

Ion Exchange and Organs

As well as the local problems of ion exchange, large-bodied organisms, such as human beings, must con-

trol ion levels throughout their whole body. They do this by managing uptake and rejection of ions selectively. Thus it is necessary to ingest sufficient but not too much of many ions such as Na^+ , K^+ , Cl^- and HPO_4^{2-} . The monitoring and rejection organ is the kidney. The kidney membranes act as complicated ion exchange systems. However, the brain apparently requires special ionic conditions, since cerebrospinal fluids of quite different composition from blood.

Ion Exchange and Pollution

Many unusual elements enter environmental waters due to mining and industrial processing of minerals. Several of these elements are toxic and we note especially lead and mercury. There is considerable interest today in the removal from cells of poisonous elements such as Hg^{2+} , Pb^{2+} and AsO_4^{3-} . Once again, even in bacteria, special proteins recognize these ions and either transfer them directly across membranes or release them to specialized pumps for energized movement out of the cell. While bacteria have evolved detoxifying processes, higher animals have not, so humans have to take action to remove the offending elements. The application of a drug may force the offensive element to exchange from the site where it causes damage, becoming bound to the drug when it is excreted.

Conclusion

While ion exchange appears to be an extremely simple idea, it is used in remarkably complicated ways in living organisms. Of course, we do not know how life began but perhaps the earliest step in the direction of the development of these organized chemical systems was the formation of an ion gradient across a membrane. Once such a gradient had formed, possibly of the proton, ion exchange could be used to move some elements out of cells and others into cells. These ions could be inorganic or organic. The movements became more complicated as more membrane containments developed in evolution. Within each compartment ions could bind to form complexes or precipitates by exchange processes. We know that cells have many different kinds of ion gradient through this exchange: some relate to energy storage and some to messages by release of the gradients. Recently evolved systems are calcium triggering of muscle and sodium/potassium currents in nerves. The restoration of the gradients is very frequently energized by ion exchange across membranes. This leads us to the tantalizing problem of the movement of ions in the brain. Are ion exchange processes deeply involved in storage, memory, and in thinking? We know that the brain is an electrolytic device and hence ion movements are always active. Clearly, we could speculate at length on this topic, but what is really required is more experimental evidence concerning ion exchange in organisms and especially in the brain.

Introduction

Isolation and separation of specific molecules is used in almost all areas of biosciences and biotechnologies. Separation technology is thus one of the most important areas for further study and development. New separation techniques, capable of treating dilute solutions or solutions containing only minute amounts of

target molecules in the presence of vast amounts of accompanying compounds in both small and large-scale processes, even in the presence of particulate matter, are necessary.

In the area of biosciences, isolation of biologically active compounds and xenobiotics is usually performed using a variety of chromatography procedures, affinity chromatography being one of the most important. Affinity ligand techniques currently represent the most powerful tool available for downstream processing both in terms of their selectivity and recovery. The strength of column affinity chromatography has been shown in thousands of successful applications, especially on a laboratory

scale. The disadvantage of standard column procedures is the impossibility of such systems to cope with samples containing particulate material so they are not suitable for use in the early stages of the isolation/purification process where suspended solid and fouling components are present. In this case magnetic affinity batch adsorption, applications of magnetically stabilized fluidized beds or magnetically modified two-phase systems have shown their usefulness.

The basic principle of magnetic affinity separation is very simple. Magnetic carriers bearing an immobilized affinity ligand or magnetic biopolymer particles are mixed with a sample containing target compound(s). Samples may be crude cells lysates, whole blood, plasma, urine, cultivation media, water, soil extracts and many others. Following an incubation period when the target compound(s) bind to the magnetic affinity particles, the whole magnetic complex is easily and rapidly removed from the sample using an appropriate magnetic separator. After washing, the isolated target compound(s) can be eluted and used for further work.

Magnetic separation techniques have several advantages in comparison with standard separation procedures. The separation process can be performed directly in crude samples containing suspended solid material. Due to the magnetic properties of the magnetic affinity particles (and the diamagnetic properties of the majority of the contaminating molecules and particles present in the treated sample) they can be relatively easily and selectively removed from the sample. In fact, magnetic separation is the only feasible method for recovery of small magnetic particles (diameter ca. 0.1–1 μm) in the presence of biological debris and other fouling material of similar size. Moreover, the power and efficiency of magnetic separation procedures is especially useful for large-scale operations. The magnetic separation techniques are also the basis of various automated procedures, especially magnetic particle-based immunoassay systems for the determination of a variety of analytes. The basic equipment for laboratory experiments is very simple. Magnetic particles of various types are easily available, as well as magnetic separators. A short description is given below.

Equipment and Materials

Magnetic carriers with immobilized affinity ligand or magnetic particles prepared from a biopolymer exhibiting affinity for the target compound(s) are used to perform the isolation procedure. Magnetic separators are necessary to recover magnetic particles from the system.

Magnetic carriers and adsorbents are commercially available and can also be prepared in the laboratory. Such materials are usually available in the form of magnetic particles prepared from various synthetic polymers, biopolymers or porous glass, or magnetic particles based on inorganic magnetic materials such as surface-modified magnetite can be used. In fact, many of the particles behave like paramagnetic or superparamagnetic ones responding to an external magnetic field, but not interacting themselves in the absence of a magnetic field. This is important due to the fact that magnetic particles can be easily resuspended and remain in suspension for a long time. The diameter of the particles is from ca. 50 nm to ca. 10 μm . Magnetic particles having a diameter larger than ca. 1 μm can be easily separated using simple magnetic separators, while separation of smaller particles (magnetic colloids with a particle size ranging between tens and hundreds of nanometers) may require the use of high-gradient magnetic separators.

Commercially available magnetic particles can be obtained from a variety of companies. In most cases polystyrene is used as a matrix, but carriers based on cellulose, agarose, silica, porous glass or silanized magnetic particles are also available. Particles with immobilized affinity ligands are available, oligodeoxythymidine, streptavidin, antibodies, protein A and protein G being used most often. Magnetic particles with such immobilized ligands can serve as generic solid phases to which native or modified affinity ligands can be immobilized (e.g. antibodies in the case of immobilized protein A, protein G or secondary antibodies, biotinylated molecules in the case of immobilized streptavidin or adenylated molecules in the case of immobilized oligodeoxythymidine). In exceptional cases, enzyme activity may decrease as a result of usage of magnetic particles with exposed iron oxides. In this case encapsulated microspheres, having an outer layer of pure polymer, are safer. In **Table 1** is given a list of companies producing and selling magnetic particles of various types.

In the laboratory, magnetite (or similar magnetic materials such as maghemite or ferrites) particles are usually surface modified by silanization. This process modifies the surface of the inorganic particles so that appropriate function groups become available, which enable easy immobilization of affinity ligands.

Biopolymers such as agarose, chitosan, κ -carrageenan and alginate can be easily prepared in a magnetic form. In the simplest way, the biopolymer solution is mixed with magnetic particles and after bulk gel formation the magnetic gel formed is broken into fine particles. Alternatively, biopolymer solution containing dispersed magnetite is dropped into a mixed hardening solution or a water-in-oil suspension

Table 1 Examples of commercially available magnetic particles suitable for magnetic affinity separations

Manufacturer/supplier	Name of particles	Diameter (μm)	Polymer composition/surface modification	End groups/activation possibility	Immobilized ligands

technique is used to prepare spherical particles. Basically the same procedures can be used to prepare magnetic particles from synthetic polymers such as polyacrylamide or poly(vinylalcohol).

In one of the approaches used, standard affinity chromatography material is post-magnetized by pumping the water-based ferrofluid through the column packed with the sorbent. Magnetic material accumulates within the affinity adsorbent pores thus modifying the chromatography material into magnetic form.

Some affinity ligands (usually general binding ligands) are already immobilized to commercially

available carriers (see Table 1). To immobilize other ligands to both commercial and laboratory-made magnetic particles, standard procedures used in affinity chromatography can be employed. Usually functional groups available on the surface of magnetic particles such as -COOH, -OH or -NH₂ are used for immobilization; in some cases, magnetic particles are already available in the activated form (e.g. tosyl activated).

Magnetic separators are necessary to separate the magnetic particles from the system. In the simplest approach, a small permanent magnet can be used, but various magnetic separators employing strong

rare-earth magnets can be obtained at reasonable prices. Commercial laboratory scale *batch magnetic separators* are usually made from magnets embedded in disinfectant-proof material. The racks are constructed for separations in Eppendorf microtubes, standard test tubes or centrifugation cuvettes. Some have a removable magnetic plate to facilitate washing of separated magnetic particles (Figure 1). Other types of separators enable separations from the wells of microtitration plates and the flat magnetic separators are useful for separation from larger volumes of suspensions (up to ca. 500–1000 mL).

Flow-through magnetic separators are usually more expensive and more complicated, and *high-gradient magnetic separators* (HGMS) are typical examples (Figure 2). Laboratory-scale HGMS are constructed from a column packed with fine magnetic-grade stainless-steel wool or small steel balls placed between the poles of an appropriate magnet. The suspension is pumped through the column, and magnetic particles are retained within the matrix. After removing the column from the magnetic field, the particles are retrieved by flow and usually by gentle vibration of the column.

Basic Principles of Magnetic Affinity Separations

In general, magnetic affinity separations can be performed in two different modes. In the *direct method* an appropriate affinity ligand is directly coupled to the magnetic particles or biopolymer exhibiting affinity towards target compound(s) is used in the course of preparation of magnetic affinity particles. These particles are added to the sample and target compounds then bind to them. In the *indirect method* the free affinity ligand (in most cases an appropriate antibody) is added to the solution or suspension to enable the interaction with the target compound. The resulting complex is then captured by appropriate

Figure 2 (See Colour Plate 62). A typical example of laboratory-scale high-gradient magnetic separators. OctoMACS Separator (Miltenyi Biotec, Germany) can be used for simultaneous isolation of mRNA. Courtesy of Miltenyi Biotec, Germany.

magnetic particles. In case antibodies are used as free affinity ligands, magnetic particles with immobilized secondary antibodies, protein A or protein G are used for capturing the complex. Alternatively, the free affinity ligands can be biotinylated and magnetic particles with immobilized streptavidin or avidin are used to capture the complexes formed. In both methods magnetic particles with isolated target compound(s) are magnetically separated and then a series of washing steps are performed to remove the majority of contaminating compounds and particles. The target compound is then usually eluted, but for specific applications (especially in molecular biology, bioanalytical chemistry or environmental chemistry) they can be used still attached to the particles, such as in the case of polymerase chain reaction, magnetic ELISA, etc.

The two methods perform equally well, but, in general, the direct technique is more easily controlled. The indirect procedure may perform better if affinity ligands have poor affinity for the target compound.

In some cases, nonspecific binding of accompanying compounds can be observed due to the specific properties of the magnetic particle material. In this case, pretreatment with the magnetic carrier without immobilized affinity ligand or with immobilized nonspecific molecules will usually help. The nonspecific binding can be also minimized by adding a nonionic detergent both in the sample and in the washing buffers after isolation of the target.

In most cases, *magnetic batch affinity adsorption* is used to perform the separation step. This approach represents the simplest procedure available, enabling the whole separation to be performed in one test-tube or flask. If larger magnetic particles (with diameters

ca. $> 1 \mu\text{m}$) are used, simple magnetic separators can be employed. If magnetic colloids (diameters ranging between tens and hundreds of nanometers) are used as affinity adsorbents, high-gradient magnetic separators have usually to be used to remove the magnetic particles from the system.

Alternatively, *magnetically stabilized fluidized beds* (MSFB), which allow continuous separation, can be used. The use of MSFB is an alternative to conventional column operation, such as packed bed or fluidized bed, especially for large-scale purification of biological products. Magnetic stabilization enables the expansion of a packed bed without mixing of solid particles. High column efficiency, low pressure drop and elimination of clogging can be attained.

Biocompatible two-phase systems, composed for example from dextran and polyethylene glycol, are often used for isolation of biologically active compounds, subcellular organelles and cells. The separation of the phases can be accelerated by the addition of fine magnetic particles or ferrofluids to the system followed by the application of a magnetic field. Magnetically enhanced phase separation usually increases the speed of phase separation by a factor of about 10 in easy systems, but it may increase by a factor of many thousands in difficult systems.

Examples of Magnetic Affinity Separations of Biologically Active Compounds and Xenobiotics

Magnetic affinity separations have been successfully used in various areas, such as molecular biology, biochemistry, immunochemistry, enzymology, analytical chemistry and environmental chemistry. Tables 2–4 show some selected applications of these techniques.

At present, magnetic affinity separation techniques are used especially in molecular biology for the isolation of RNA, DNA and oligonucleotides. Almost all the procedures employ the same basic principle, based on the hybridization of immobilized oligonucleotides and target structures. There are several companies offering oligodeoxythymidine immobilized on magnetic particles, which can be effectively used for rapid isolation of highly purified, intact poly A⁺ mRNA from eukaryotic total RNA. Poly A⁺ mRNA has been successfully isolated from various samples, such as cells, animal and plant tissues, blood, cells isolated by immunomagnetic separation, paraffin-embedded tissues, etc. Also cells and tissues containing high RNase activities can be used for mRNA isolation. The separated mRNA can be eluted from the beads by lowering the ionic strength of the elution buffer and used for further applications (Northern blotting, dot-blot hybridization, hybridization probes) or used still bound to magnetic particles (cDNA synthesis, construction of solid-phase cDNA library, etc.). Enzymatic downstream applications are usually not inhibited by the presence of magnetic particles. The covalent binding of oligodeoxythymidine to magnetic particles makes it possible to regenerate the specific adsorbent and to reuse it up to four times.

Isolation of DNA and RNA can be simply performed using biotinylated specific nucleic acids or oligonucleotides immobilized on magnetic particles with immobilized streptavidin. Usually large binding capacity can be achieved resulting in excellent reaction kinetics and high efficiency of the procedure. In addition, magnetic silica particles have been used for simple isolation of DNA and RNA from various biological samples and also to purify DNA fragments after agarose gel electrophoresis.

Table 2 Typical examples of magnetic separations of nucleic acids

Nucleic acid	Magnetic system used	Typical examples
RNA	Magnetic particles with immobilized oligo (dT) ₂₅	Eukaryotic poly A ⁺ mRNA, viral poly A ⁺ RNA
	Magnetic particles with immobilized specific oligonucleotides	tRNA
DNA	Dynabeads DNA DIRECT	PCR-ready DNA
	Biotinylated cloned genomic DNA immobilized on Dynabeads Streptavidin	cDNA
	Dynabeads M-280 Streptavidin with immobilized biotinylated oligonucleotide complementary to the lacZ region	M13 single-stranded DNA
	Magnetic particles with immobilized pyrimidine oligonucleotide	Double-stranded target DNA (triple helix formation)
	COOH-terminated magnetic beads (under specific concentrations of polyethylene glycol and salt)	Double-stranded DNA, PCR products, M13 single-stranded DNA
	Magnetic silica particles	DNA

Table 3 Selected examples of magnetic affinity separation of proteins

<i>Isolated protein</i>	<i>Magnetic system used</i>	<i>Typical examples</i>
Enzymes	Sub-micron ferrite particles with immobilized soybean trypsin inhibitor	Trypsin
	Ferrofluid-modified 5'-AMP-Sepharose 4B	Alcohol dehydrogenase
	Magnetic agarose beads with immobilized dye	Lactate dehydrogenase
	Magnetic chitin	Lysozyme
	Dynabeads with immobilized polyclonal antibodies	Angiotensin-converting enzyme
	Iminodiacetic acid coupled to magnetic agarose and charged with Zn^{2+}	Angiol-TEM- β -lactamase
	Alginate-magnetite beads	Pectinase
Antibodies	Magnetic affinity aqueous two-phase system	Hexokinase
	Magnetic particles with immobilized antibodies against human IgG	Human IgG antibodies
	Magnetic particles with immobilized protein A or protein G	Antibodies
Lectins	Human serum albumin immobilized onto ferromagnetic dactron	Antibodies against human serum albumin
	Magnetic cross-linked chitosan	<i>Solanum tuberosum</i> lectin
Receptors	Dynabeads M-450 sheep anti-mouse IgG ₁ with immobilized monoclonal antibody	Human transferrin receptor
	Magnetic particles with immobilized oligonucleotide containing EcdR binding sequence	Ecdysteroid receptor (EcdR) from <i>Drosophila melanogaster</i>
Other proteins	Magnetic particles with immobilized DNA/RNA fragment containing the specific binding sequence	DNA/RNA binding proteins
	Magnetic particles with immobilized <i>m</i> -aminophenylboronic acid	Glycated haemoglobin
	Organomercurial-agarose magnetic beads	Transcriptionally active chromatin restriction fragments with accessible histone H3 thiols
	Ni-NTA Magnetic agarose beads	6xHis-tagged proteins

Table 4 Selected examples of magnetic separation of low-molecular-weight biologically active compounds and organic and inorganic xenobiotics

<i>Type of compound</i>	<i>Magnetic system used</i>	<i>Typical examples</i>
Biologically active compounds	Magnetic particles with immobilized aldosterone antiserum	Aldosterone
	Molecularly imprinted polymer containing magnetic iron oxide	(S)-propranolol
	Magnetic charcoal	Separation of free antigens in radioimmunoassays
Organic xenobiotics	Magnetic particles with immobilized Cu-phthalocyanine	Polyaromatic hydrocarbons, triphenylmethane dyes
	Magnetic polyethyleneimine microcapsules	Carcinogens
	Magnetic particles with immobilized specific antibodies	Pesticides, polyaromatic hydrocarbons, TNT, PCBs
	Bacterial cells adsorbed to magnetite	Chlorinated hydrocarbons and pesticides
	Magnetic charcoal	Water-soluble dyes, pesticides
Inorganic xenobiotics	Magnetic chitosan	Cu^{2+} ions
	Cells of <i>Enterobacter</i> spp. immobilized on magnetite	Ni^{2+} ions
	Magnetic cross-linked cell walls of <i>Saccharomyces cerevisiae</i>	Ions of heavy metals
	Magnetotactic bacteria	Ions of heavy metals
	Solvent extractants on magnetic microparticles	Radionuclides

In the case of protein separation no simple strategy for magnetic affinity separations exists. Various affinity ligands have been immobilized on magnetic particles, or magnetic particles have been prepared from biopolymers exhibiting affinity for target enzymes or lectins, as shown in Table 3. Immunomagnetic particles, i.e. magnetic particles with immobilized specific antibodies against the target structures, have been used for the isolation of various antigens, both molecules and cells and can thus be used for the separation of specific proteins. Enzyme isolation is usually performed using immobilized inhibitors, cofactors, dyes or other suitable ligands, or magnetic beads prepared from affinity biopolymers are used. A general procedure, especially from the point of view of recombinant oligohistidine-tagged proteins, is based on the application of metal chelate magnetic adsorbents. Another general procedure employs immobilized protein A or protein G for the specific separation of immunoglobulins from ascites, serum and tissue culture supernatants.

Magnetic separation of low-molecular-weight biologically active compounds has been used in the course of their determination by various types of immunoassays. Usually immunomagnetic particles directly capture the target analyte, or magnetic particles with immobilized streptavidin are used to capture the complex of biotinylated primary antibody and the analyte. The separated analyte is then determined using an appropriate method.

Isolation and separation of organic and inorganic xenobiotics from environmental and clinical samples using magnetic techniques may find useful applications in the near future. Immobilized copper phthalocyanine dye has an affinity for planar organic compounds, such as polyaromatic hydrocarbons with three and more fused aromatic rings in their molecules, and for triphenylmethane dyes, both groups representing real or potential carcinogens and mutagens. Immunomagnetic separation of xenobiotics such as pesticides, TNT or PCBs is used as a first step in the course of their immunoassay.

Magnetic solid-phase extraction (MSPE) enables preconcentration of target analytes (e.g. environmental contaminants) from large volumes of solutions or suspensions using relatively small amount of magnetic specific adsorbent. This procedure can substitute the standard liquid-liquid and solid-phase extraction procedures.

Future Perspectives

The isolation and separation of biologically active compounds and xenobiotics using magnetic affinity techniques are a relatively new approach and still

under development. Due to the commercial availability of magnetic affinity particles and kits these techniques are currently used mainly in molecular biology (especially for separation of nucleic acids) and as parts of the kits for the determination of selected analytes using magnetic ELISA and related techniques (especially determination of clinical markers and environmental contaminants). Up to now small-scale separations prevail and thus the full potential of these techniques has not been fully exploited.

It can be expected that further development will be focused on two areas. The first one will be oriented to the laboratory-scale application of magnetic affinity separation techniques in biochemistry and related areas (isolation of a variety of both low- and high-molecular weight substances of various origins directly from crude samples thus reducing the number of purification steps) and in biochemical and environmental analysis (application of immunomagnetic particles for separation of target analytes from a mixture followed by their detection using ELISA and related principles). Such a type of analysis enables portable assay systems to be constructed for the detection and determination of environmental contaminants directly on site or for near-patient analysis of various disease markers. Alternatively, fully automated systems for the detection of clinical markers will be constructed.

In the second area, larger-scale (industrial) systems will be developed and used for the isolation of biologically active compounds directly from the crude culture media, wastes from food industry, etc. It is not expected that large amounts of low-cost products will be isolated using magnetic techniques, but attention will be directed to the isolation of minor, but highly valuable components present in raw materials. Of course, prices of magnetic carriers have to be lowered, and special types of low-cost, biotechnology-applicable magnetic carriers prepared by simple and cheap procedures have to become available. Magnetic separations could thus be the technique for the 21st century.

BIOMEDICAL APPLICATIONS

Gas Chromatography – Mass Spectrometry

V. Garner, Stockport, UK

Copyright © 2000 Academic Press

Introduction

The tremendous technological developments that have followed the initial interfacing of gas chromatographs with mass spectrometers together with the phenomenal advances in computerized data handling have provided an analytical technique that finds practically universal application. The biomedical sciences afford an enormous range of applications of this instrumentation where its full potential as a primary method for the separations and identification of extremely complex mixtures is clearly demonstrated.

The applications can be grouped into three broad categories based upon the nature of the analytes:

- Small volatile molecules, e.g. metabolites, xenobiotics (drugs, toxins, etc), food components
- Large labile molecular species, e.g. biomacromolecules and even whole cells
- Isotopomers (molecules differing only in isotopic composition), e.g. tracer studies, isotopic labelling, breath gas diagnostics, natural abundance studies

The analysis of small volatile molecules, perhaps after derivatization, is the major application area; particular biomedical applications in clinical chemistry

and occupational hygiene are illustrated below. Others are exemplified under the headings sport, environment, food and forensics. The analysis of biomacromolecules and whole cells is another rapidly expanding field but using other mass spectrometric and separatory techniques (electrospray, atmospheric pressure and matrix assisted laser desorption ionization; see also LC–MS, CE–MS). Gas chromatography–mass spectrometry (GC–MS) of pyrolysates can provide information about otherwise intractable materials.

The elucidation of mechanisms and biochemical pathways using tracer and labelling techniques is an example of the third category of applications which is also a rapidly expanding area with the wider availability of stable as opposed to radioactive labelled compounds. The ability to separate and distinguish between components in a complex mixture that differ solely in their isotopic composition allows exogenous materials to be distinguished from endogenous species; it also provides a means of improving quantitation (via isotope dilution) and allows dynamic studies of metabolism or dysfunction to be undertaken. It is this latter area of GC–SIRMS (GC–stable isotope ratio MS) that will be emphasized.

Analysis of Small Volatile Molecules

Instrumentation

The majority of instruments utilize capillary columns thereby allowing relatively simple connection to the mass spectrometer. Earlier systems used packed columns that required some form of separator in order

to reduce the amount of carrier gas entering the mass spectrometer ionization chamber. A 5% poly(diphenyldimethylsiloxane) stationary phase is frequently used because of its wide general applicability and stability. Samples can be introduced using an autoinjector or manually by syringe; headspace gases, solutions in volatile solvents, solid-phase microextraction (SPME) systems and thermal desorption with cryofocussing can all be used. In some cases it is necessary or advisable to derivatize the sample in order to enhance its thermal stability.

Mass spectrometers of any type can be coupled, from huge magnetic sector machines to time-of-flight systems and the small 'bench-top' quadrupole or ion trap instruments. When the mass spectrometer is op-

erated in positive ion mode with electron impact ionization at 70 eV spectra generated can be compared with those in the extensive databases organized by NIST and Wiley. Using computerized file-handling techniques, spectra can be compared very rapidly and a list of possible compounds can be compiled. The mass spectrometer can also be operated in negative ion mode which allows improved sensitivity with particular analytes especially with chemical ionization.

Applications

Figure 1 shows typical results from a GC-MS study using a bench-top quadrupole system. The sample was obtained by extraction of serum taken after administration of an oestradiol prodrug. The upper

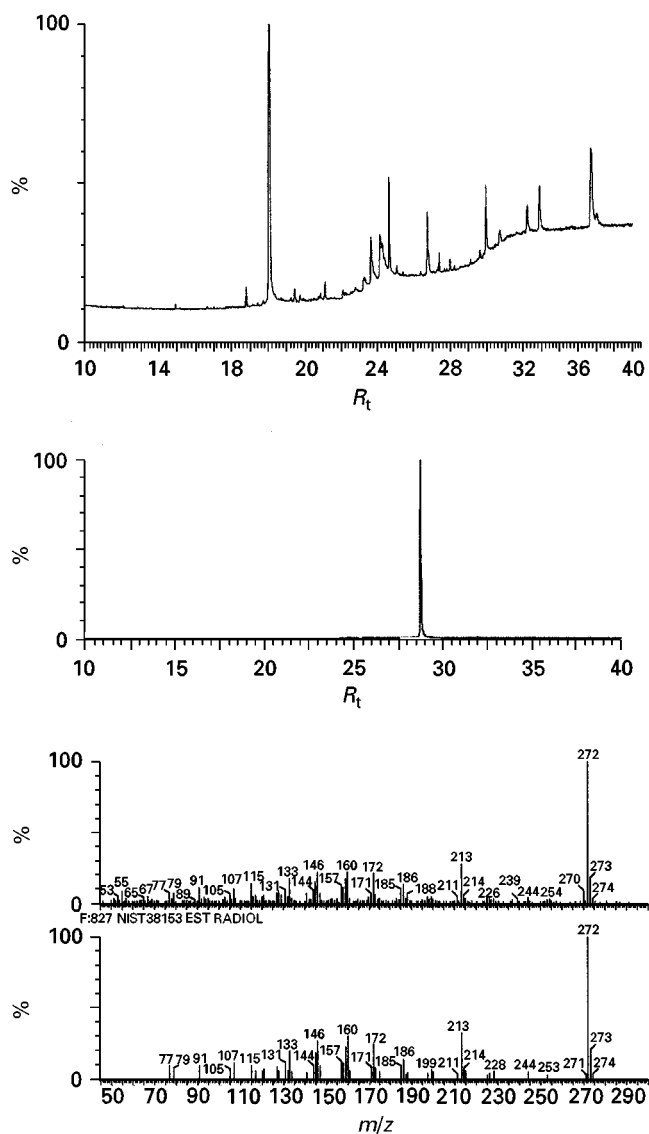

Figure 1 GC-MS of serum extract following oestradiol prodrug administration: (top) total ion chromatogram; (middle) mass chromatogram for $m/z = 272$; (bottom) mass spectrum for peak at $R_t = 28.76$ min and NIST library spectrum for oestradiol.

Figure 2 Mass chromatogram for $m/z = 74$ identifying FAMES.

trace shows the total ion chromatogram (TIC), the second trace shows the mass chromatogram for $m/z = 272$ which is diagnostic for oestradiol. The mass spectrum obtained for this component and the NIST library match are the lower traces.

Use of mass chromatograms of diagnostic ions allows facile recognition of homologous series such as fatty acid methyl esters (FAMES). **Figure 2** shows the mass chromatogram for $m/z = 74$ for the FAME derivatives prepared from an archeological sample; this valuable information assisted in the interpretation of the pottery artifact.

The signal at $m/z = 74$ is due to methyl ethanoate formed in the mass spectrometer by a McLafferty rearrangement shown in **Figure 3**. This process can occur with any FAME having an available hydrogen atom at position 4 and thus provides a useful diagnostic ion.

Selected ion recording (SIR) measures the ion current for a restricted range of ions instead of the whole spectrum. This is of particular use in biomonitoring studies for example where the analyte is well characterized from the chromatographic and spectrometric point of view, affording improved sensitivity and precision.

Figure 4 is a graphical representation of the data from an occupational health study of urinary amines: paired samples of urine taken at the beginning and end of a working day were analysed for a particular aromatic amine. A protocol was used that freed the amine from excreted conjugates followed by ex-

Figure 4 Urinary amine concentrations of paired samples.

traction and derivatization. The graph emphasizes the difference between the amounts of amine in the paired samples; although the values were well below regulatory limits, those from the fifth pair led to a change in working practice for that donor.

Amines can be converted into perfluoroacyl derivatives which are more stable thermally and chemically; such derivatives give improved sensitivity in electron-capture detectors and this is also manifest in negative ion chemical ionization mass spectrometry. This approach can be adopted for the analysis of materials that form relatively stable gas phase anions in the mass spectrometer. **Figure 5** shows data from another typical example: prostanoids such as $\text{PGF}_{2\alpha}$ are converted into the t-butyldimethylsilyl ether/pentafluorobenzoyl ester derivatives. Under negative ion chemical ionization conditions using either methane or ammonia as reagent gas, the ester function is lost in a fragmentation reaction to form a fragment ion at $m/z = 695$ corresponding to the silyl ether carboxylate anion shown in the figure. This ion shows satellites due to silicon and carbon isotopes at 696 and 697 that are in accord with calculated distributions. Detection levels for this analyte are in the low $\text{pg } \mu\text{L}^{-1}$ (ppm) range for full scan data and $\text{fg } \mu\text{L}^{-1}$ (ppb) range with selected ion recording.

The final example of this first group of applications involving small volatile species crosses the boundary into analysis of large intractable materials and concerns a pyrolysis study. Occasionally there may be insufficient sample to carry out a normal extraction prior to GC-MS analysis, this is particularly so with conserved archeological material and microscopic biopsy samples. In such circumstances, microscale sealed vessel pyrolysis GC-MS can be applied: **Figure 6** shows the TIC obtained from a hair sample (2 mg) taken from an Egyptian mummy. The individual components of the pyrolysate can be identified

Figure 3 McLafferty rearrangement in a FAME $\text{M}^{+\bullet}$ to form $m/z = 74$.

Figure 5 Mass spectrum of derivatized $\text{PGF}_{2\alpha}$ in negative ion chemical ionization and structure of anion corresponding to $m/z = 695$.

by comparison with library spectra and interpreted in terms of the mummification process.

This pyrolysis method can be applied to other complex analytes including whole cells in order to investigate occluded materials or for the identification of chemical modification of biopolymers such as starch.

The quantitative analysis of halogenated dibenzodioxins and -furans in biological (and environmental) matrices is a good example of the combination of high resolution GC (HRGC) and MS (HRMS) technologies using the isotopes of chlorine and carbon

Figure 6 Total ion chromatogram from GC-MS of pyrolysis products from archaeological hair sample.

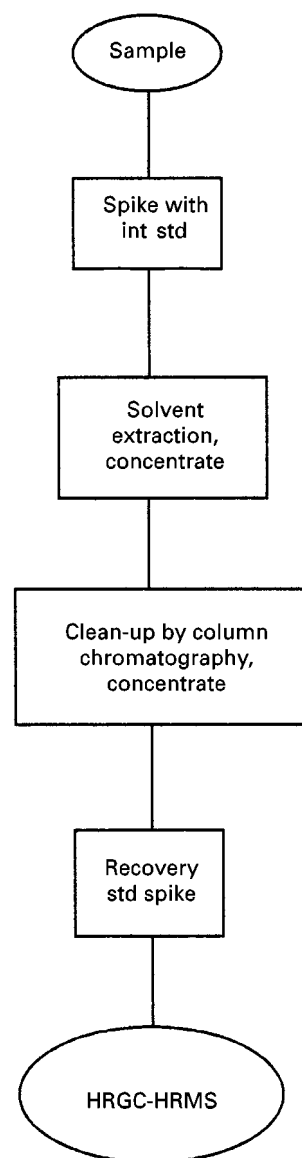

Figure 7 Protocol for pretreatment of dioxin/furan samples prior to HRGC-HRMS.

to facilitate identification and quantification. Prior to any instrumental analysis, the flesh, vegetation or other material has to be prepared according to a quality assured protocol that is summarized in Figure 7.

Intrinsic to the procedure is the use of standards: the first standard to be added is $^{13}\text{C}_{12}$ -2,3,7,8-tetrachlorodibenzodioxin upon which quantitation is based. Another standard, $^{13}\text{C}_{12}$ -1,2,3,4-tetrachlorodibenzodioxin is added after the chemical manipulation of the sample is complete and immediately prior to GC-MS analysis. Comparison of the signals from the two standards then allows the efficiency of the extraction process to be assessed. Typical data sets are shown in Figures 8 and 9: both show four traces, the upper two traces are the high resolution

Figure 8 HRGC–HRMS SIR data from dioxin/furan analysis of meat extract.

SIR data for $m/z = 319.8965$ and 321.8936 corresponding to the molecular ions of tetrachlorodibenzodioxins (TCDD), i.e. $C_{12}H_4(^{35}Cl)_4O_2$ and $C_{12}H_4(^{35}Cl_3^{37}Cl)O_2$ respectively. The lower two traces in each case correspond to the ions of $m/z = 331.9368$ and 333.9339 for the ^{13}C -isotopomers, i.e. $^{13}C_{12}H_4(^{35}Cl)_4O_2$ and $^{13}C_{12}H_4(^{35}Cl_3^{37}Cl)O_2$ for the two standards.

The data shown in Figure 8 represents TCDD levels below regulatory limits whereas those in Figure 9 (from an environmental sample) were significantly higher.

Analysis of Isotopomers

The above example shows the dual benefits of high resolution instrumentation and isotope dilution to effect precise quantification and identification. There are many other examples of this type of application that relies upon analysis of the intact analyte molecule in the mass spectrometer. The

second group of applications follows a different approach in which isotopomeric components are initially separated then converted into light gases, carbon dioxide, hydrogen and nitrogen. It is these latter materials that are investigated in the isotope ratioing mass spectrometer whereby the ratios of carbon, hydrogen, oxygen and nitrogen isotopes are determined with much greater precision.

Instrumentation

The design of the mass spectrometer is extremely simple comprising an electron impact ionization source, a very stable magnetic analyser and triple Faraday cup collector (Figure 10A).

The combustion interface incorporates a furnace containing heated copper oxide which converts organic chemicals in the column effluent into carbon dioxide and water; a cold trap is used to remove the water vapour. Conversion of the individual components into the same chemical species such as carbon dioxide removes some of the variables that arise from

Figure 9 HRGC–HRMS SIR data from dioxin/furan analysis of an environmental sample.

different sample behaviour and isotopomeric distribution commonly observed in electron impact ionisation. Simultaneous recording of the ion beams at $m/z = 44, 45$ and 46 (corresponding to $^{12}\text{C}^{16}\text{O}_2$, $^{13}\text{C}^{16}\text{O}_2$ and $^{12}\text{C}^{16}\text{O}^{18}\text{O}$ respectively for carbon dioxide) using three separate Faraday collectors minimizes background signal fluctuation. These differences result in a dramatic improvement in the stability of the signal allowing determination of isotopic ratios at about 10^{-5} at%.

Figure 10B shows a graphical output from the three collectors for three reference gas pulses and one sample.

The units used to express the relative difference in isotopic abundances are either atoms% (at%) or delta (δ , per mil or ‰).

$$\text{At\%} = \left(\frac{\text{no. of minor atoms}}{\text{no. of major atoms}} \right) \times 100$$

$$\delta = \frac{(\text{sample ratio} - \text{reference ratio})}{\text{reference ratio}} \times 1000$$

Applications

The use of stable isotopes such as ^2H , ^{13}C , ^{15}N or ^{18}O instead of the radioactive analogues removes all risks associated with radiation but the introduction of an isotopic substitution at the site of a rate-limiting reaction can introduce kinetic isotope effects. Thus an artificial change to the natural isotopic distribution could in theory alter the kinetics of the biochemical process and thereby affect the overall metabolic rate. Many theoretical calculations and experimental observations have been made: the greatest differences occur with hydrogen replacement with a maximum relative rate ratio ($k_{\text{H}}/k_{\text{D}}$) of 18. The differences with other isotopic replacements are much smaller: $^{12}\text{C}/^{13}\text{C}$ up to 1.25; $^{14}\text{N}/^{15}\text{N}$, 1.14; $^{16}\text{O}/^{18}\text{O}$, 1.119 and $^{32}\text{S}/^{34}\text{S}$, 1.05. This particular risk is however even smaller than that with the corresponding radiolabels whose values are $^1\text{H}/^3\text{H}$, 60 (max) and $^{12}\text{C}/^{14}\text{C}$, 1.5.

Breath Gas Testing Using $^{13}\text{CO}_2$

The basic principle is illustrated in **Figure 11**.

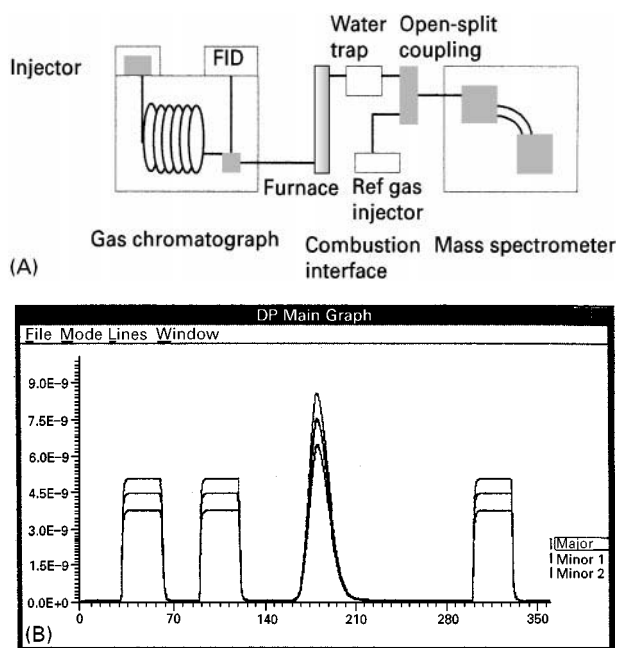

Figure 10 (A) Schematic representation of a GC-SIRMS system (B) Graphical output from SIRMS of two reference gas pulses, sample, reference gas pulse.

Oral administration of either a solution of the ^{13}C -labelled substrate in water or fruit juice or a suspension in a flavoured colloidal preparation is usually preferred to intravenous injection to emphasize the 'non-invasive' approach. Breath gas is the easiest means of sample collection. However, there are others including saliva, urine, faeces, milk, hair, nails

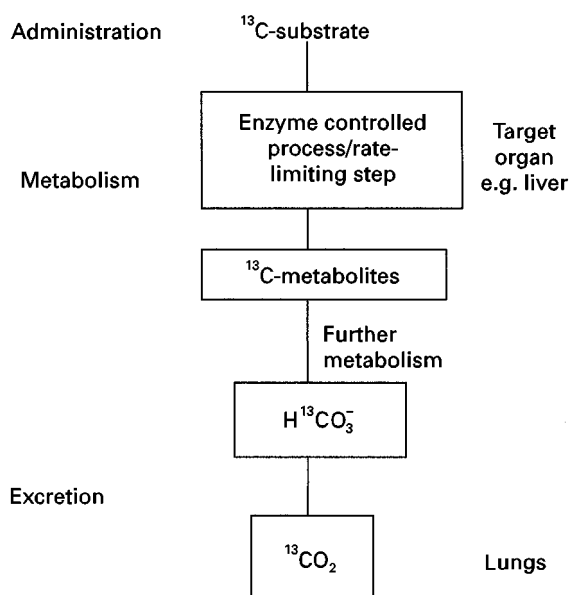

Figure 11 Schematic diagram of procedure for breath gas testing.

or blood, gastric fluid or muscle. These latter requiring clinical intervention.

The ^{13}C -urea breath test for *Helicobacter pylori* A characteristic of this bacterium is its high urease activity; this is exploited by administering a solution of ^{13}C -urea (1 mg kg^{-1} body weight, ca. 75 mg for an average adult) and investigating the effect on the level of $^{13}\text{CO}_2$ in the breath after a short time interval of about 20–30 min. If the bacterium is present, the urea is converted into bicarbonate which appears in the breath as $^{13}\text{CO}_2$; in its absence the isotopic distribution remains unchanged (Figure 12).

Typical results from a group of untreated and treated patients are shown in Figure 13: differences between the pre- and post-breath samples (referring to ^{13}C -urea administration) of more than 3‰ are taken to indicate infection.

Other metabolic breath tests Introduction of a variety of ^{13}C -labelled substrates into a test meal that is ingested by the patient can be used to monitor particular metabolic functions *in vivo* without the need for invasive surgery and the collection of biopsy samples and subsequent *in vitro* biochemical investigation. Thus gastric emptying rates can be measured using octanoic acid labelled at position 1 with ^{13}C ; abnormalities in the cytochrome P450 pathway in liver metabolism can be determined using a variety of substrates shown in Figure 14 with typical data shown in Figure 15.

These data show that measurements taken after a time interval of one hour (after dosing with the labelled substrate) allow unambiguous detection of abnormality. A similar distinction is possible for lipid malabsorption using a range of ^{13}C -labelled triacyl glycerides. The results summarized in Figure 16 are from a study of absorption of ^{13}C -dodecanoic acid introduced intraduodenally.

Tracer studies

The facile determination of carbon isotope ratios in specific compounds extends the scope of tracer studies to include assessment of metabolic rates for a wide variety of substrates. Thus administration of specifically labelled lipids, amino acids and carbohydrates followed by GC-SIRMS analysis of fractionated serum samples allows not only the identification of

Figure 12 Chemical basis of the *Helicobacter pylori* breath test.

Figure 13 Typical results from *Helicobacter pylori* breath tests.

metabolic products but also the measurement of turn-over rates of those substrates. The sensitivity of the system is such that measurements can be made using enriched substrates (as opposed to fully labelled compounds). **Figure 17** summarizes the results of a study using ¹³C-enriched maize sugar administered at 1 g kg⁻¹ body weight then timed blood samples purified and analysed for enrichment of plasma glucose by GC-SIRMS.

The data demonstrated that even at relatively low levels of enrichment, the appearance rate could be measured.

Natural abundance measurements

Primary and secondary kinetic isotope effects, although small, lead to fractionation of isotopomers and the observed natural variations in isotopic abundances. These temporal and geographical variations can be measured using SIRMS and used to

detect adulteration and authenticity of foodstuffs and identify migration patterns of insects.

The variation in ¹³C content of a variety of natural materials is summarized in **Figure 18**. Plants convert carbon dioxide into carbohydrates by two main photosynthetic mechanisms: the Calvin–Benson cycle or the Hatch–Slack pathway. Plants such as rice, wheat, potatoes, beet or brassicas utilize C₃ intermediates and result in depleted ¹³C content (i.e. delta values are more negative) whereas maize, sugar cane and tropical fruits use C₄ intermediates that demonstrate higher ¹³C content. The differences are large enough to be translated through the food web and be measured by GC-SIRMS.

The average δ-¹³C value of honey, produced from flowers of C₃ plants by bees, is significantly lower than that of high fructose corn syrup (HFCS, produced from maize, a C₄ plant). Hence, it is possible not only to identify adulteration of honey with HFCS but also to determine its extent.

Many natural products, e.g. vanillin, are also available as synthetic products from chemical or biochemical syntheses; the distinction between natural, nature-identical and synthetic can be determined using GC-SIRMS. The natural product obtained by extraction has a generally higher δ-¹³C value (ca. –20‰) compared to fossil fuel derived material (ca. –30‰) or fermentation product (ca. –35‰).

The method can be used to distinguish exogenous materials from their endogenous counterparts; this is particularly useful in the detection of anabolic steroids' administration in meat products, animals, racehorses or athletes where conventional GC–MS

Figure 17 Appearance rates from a GC-SIRMS study of plasma glucose.

protocols have been shown to be inadequate. When the carbon isotope ratios for the major metabolites of testosterone, for example, are normalized to an endogenous reference compound such as cholesterol, the differences between testosterone-treated and untreated animals is statistically significant.

It is not only carbon that shows variability in its isotopic distribution; hydrogen and oxygen also show geographical variability that is correlated to rainfall latitude. Continuous-flow pyrolysis measurements of δD and $\delta^{18}O$ have been used to study animal migration patterns using a development of the technology described above. The use of helium as a carrier gas means that there is a large signal generated for He^+ at $m/z = 4$ and this needs to be totally resolved from the relatively small signal at $m/z = 3$ due to HD^+ . This is further complicated by the presence of ions at

$m/z = 3$ due to H_3^+ arising from an ion molecule reaction in the mass spectrometer source. This latter problem is overcome by application of a correction factor calculated from data from reference gas pulses.

The sample (e.g. insect wings, ca. 1 mg) is pyrolysed in a helium stream in a furnace containing quartz chips and nickel carbide at about $1000^\circ C$. The pyrolysis products, hydrogen, carbon monoxide and nitrogen, are separated using a packed column (1.5 m, molecular sieve 5 Å) then introduced into the mass spectrometer.

Reference pulses of hydrogen and carbon monoxide are introduced prior to the sample peaks and used to calculate the δD and $\delta^{18}O$ values for m/z 3/2 and m/z 30/28 and 29/28 (for carbon monoxide). A typical data set is:

	Sample 1	Sample 2	Sample 3
Latitude	30°	40°	50°
δD precipitation	-15‰	-33‰	-80‰
δD sample	-78‰	-92‰	-125‰
$\delta^{18}O$ sample	$+5.7\text{‰}$	$+3.8\text{‰}$	$+0.3\text{‰}$

Figure 18 Natural variation in ^{13}C content (‰) of natural materials.

Conclusion

GC-MS will continue to provide much high quality and fundamental analytical information that will allow the biomedical sciences to develop along the avenues described above for some time. Improvements in the technology of extraction and sampling will allow progressively smaller samples to be used.

The availability of relatively inexpensive and safe isotopically labelled substrates and precursors will benefit tracer studies and allow improved precision in quantitative measurements of a wide variety of analytes. GC-SIRMS will facilitate dynamic studies of metabolism and migration. The capacity to distinguish exogenous from endogenous materials is bound to be a significant and expanding area of application that will find great use in the identification of abuse, adulteration and authenticity.

Introduction

Great confusion exists in the literature on the definition of the term *bitumen*. It occurs in the earth's crust in various forms: firstly, in a dispersed state, in trace quantities; and secondly, as accumulations, where bitumen either impregnates the rock or occurs in a pure or nearly pure form. In the first half of the 20th century, the term bitumen was applied to crude oil and its natural derivatives (maltha, asphalt, ozokerite). In this original meaning, bitumens are called naphthides. The term bitumen is also used for asphalts and asphalt-like manufactured substances utilized in road construction, including products from the processing of coals and/or oil shales. In crude oils, in distillate cuts beginning with kerosene, and in distillation residues, there is a group of high molecular weight heteroorganic compounds that are lumped under the name of resins and asphaltenes. Their content may be as large as 40% in heavy crude oils.

Carbon and hydrogen constitute 80–95% of the resin and asphaltene molecules, with oxygen always present. Sulfur, nitrogen and metals are also usually present. The content of resins in crude oil (2–40%) exceeds by far (from 3 to 40 times) the content of asphaltenes (trace to 6%; usually <1%). Carboids and carbenes, which resemble asphaltenes, differ from them by having a higher oxygen content. However, they are absent in crude oils and distillate cuts. In small quantities, they are found in residues from vacuum distillation, in cracked tars, and in native and petroleum asphalts.

Bitumens and the related heat-treated asphalt are a very complex mixture of compounds with a wide range of molecular weights, which are difficult to isolate into classes of pure compounds. Resins are semi-liquid (sometimes almost solid) dark brown to black substances which have a specific gravity around 1 and a molecular weight of 500–2000 (usually 600–1000). Asphaltenes, on the other hand, are dark, amorphous powders and have a specific gravity greater than 1 and molecular weights of 1000–10 000 (average 5000). Using various methods, the observed molecular weights suggest that asphaltenes form molecular aggregates or colloids, even in dilute

solutions. The results are influenced by solvent polarity, asphaltene concentration and the temperature used. Different molecular weights of asphaltenes can be obtained by different instruments. For example, the data obtained from solution viscosity and cryoscopic method are low, whereas those obtained from the ultracentrifuge and electron microscope are high. Vapour pressure osmometry (VPO) is considered to be the most accurate method at present when a good solvent is used to disperse the asphaltenes. Because the solvent affects the degree of asphaltene aggregation, the true molecular weights of asphaltenes are generally much lower than those measured. Some of these results are listed in **Table 1**.

The asphaltene content is a variable value depending on the relative amounts and characteristics of the source material and on the procedure adopted for separation. The physical and chemical characteristics are of considerable importance: the higher boiling point components of crude oil can precipitate in certain solvents, whereas the lower boiling point components (cyclic and aromatic compounds) are soluble in solvents. Most of the studies on bitumens and asphalts are concentrated on groups of compounds with

particular physical and chemical properties. Depending on the solubility in certain solvents, asphalt or bitumen is generally fractionated into four main fractions: saturates, aromatics, resins and asphaltenes. The polarity of these fractions increases in the following order: saturates < aromatics < resins < asphaltenes. A detailed scheme for bitumen fractionation is shown in **Figure 1** and explained as follows:

1. Gas oil is propane-soluble and *n*-pentane-insoluble.
2. Resins are *n*-pentane-soluble but propane-insoluble.
3. Asphaltenes are toluene-soluble but *n*-pentane insoluble.
4. Preasphaltenes are insoluble in both *n*-pentane and toluene.

Asphaltenes are multipolymer systems containing a great variety of building blocks. The statistically average molecule contains a flat sheet of condensed aromatic systems that may be interconnected by sulfide, ether, aliphatic chains or naphthenic ring linkages. Gaps and holes appear as defect centres in the aromatic systems most likely involving free radicals. Heterocyclic atoms may be coordinated to transition

**Figure 1** Fractionation scheme of bitumen or asphalt.

metals such as vanadium, nickel and iron. Approximately five of these sheets are associated by π - π interaction. They are stacked one above the other: the distance between the sheets ranges from 0.36 to 0.38 nm, giving an overall height for a stack of 1.6–2.0 nm; the average sheet diameter appears to be 0.85–1.5 nm. The hypothetical structure of an asphaltene is shown in Figure 2.

Resins are considered smaller analogues of asphaltenes with a much lower molecular weight. The resins contain aromatic compounds substituted with longer alkyl chains and a greater number of side chains attached to the rings than asphaltenes. The combination of the saturated and aromatic characteristics of resins stabilizes the colloidal nature of asphaltenes present in the oil.

Figure 2 (A) The classification of asphaltene structure. (B) The structure of asphaltene stack. (C) The structure of one sheet of asphaltene stack.

The gas oils constitute the lowest molecular fraction of the asphalt and serve as the dispersion medium for the peptized asphaltenes. Structurally, gas oils consist mostly of naphthenic–aromatic nuclei with a greater proportion of side chains than the resins. Alkyl naphthenes predominate and straight chain alkanes are rarely present. The naphthenic content is 15–50%, with naphthenics containing two to five nuclei per molecule.

The fractionation techniques for crude oil involve solvent fractionation and precipitation, column chromatography, ion exchange and complexation methods. No matter what method is used, the important step is the isolation of asphaltenes. Of course, all these separation processes are carried out on the heavy fractions of petroleum only; usually the volatile fractions have been removed by distillation.

The most popular method of column chromatography is the fractionation into saturates, aromatics, resins and asphaltenes (SARA). Solvent fractionations have been used in the industry since 1930, becoming widely accepted between 1950 and 1970. Recently, centrifugal thin-layer chromatography (TLC) has been used to separate crude oil successfully. This method reduces the separation time and cost, as well as preserving each fraction for further study. TLC with flame ionization detector (TLC-FID) can achieve quantitative analysis quickly and simply. The combination of solvent fractionation by silica gel and ion exchange chromatography can achieve a more detailed separation showing the complexity of petroleum. The polar fraction of the crude oil is separated by ion exchange. For chromatographic methods for

bitumen or asphalt separation (SARA method, centrifugal TLC, TLC-FID and the combination of silica gel chromatography and ion exchange) are described in detail in the following sections.

The SARA Method

Background

The SARA method enables the separation of bitumen into groups. The method is an extension of column chromatography in order to permit more standardized separation. Two packed columns are employed: Firstly, a SARA column (ion exchange resins) and secondly, an activated silica gel column. The resin fractions are irreversibly retained in the SARA column, whereas the gas oil (saturates and aromatics) fraction remains in the solvent after elution of this column. The gas oil fraction can be further separated into saturates and aromatics by the activated silica gel column. A flow diagram of the SARA method is given in Figure 3. Although the SARA method has been considered as a standard separation technique for asphaltenes, there are some drawbacks to prevent it from becoming popular: it is time-consuming (it takes at least 1 week) and there is incomplete recovery (resin fraction is difficult to recover).

Separation Procedure

Separation of asphaltenes The asphaltene fraction is separated by a precipitation process. The bitumen and asphalt samples can be dissolved first in toluene to form dispersions for precipitation by another

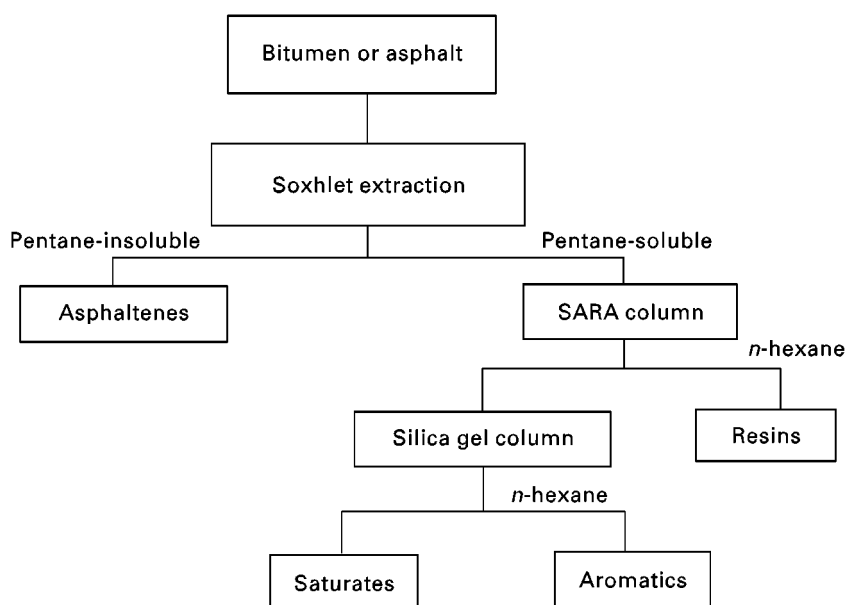

Figure 3 Flow chart of SARA separation method.

liquid. Asphaltene precipitation occurs when an excess of *n*-pentane is added to the toluene dispersion. A toluene-*n*-pentane volumetric ratio of 1 to 50 is required to ensure the precipitation of asphaltenes. After the precipitation process, the toluene dispersion can be separated into two fractions: pentane-insoluble (asphaltenes) and pentane-soluble (maltenes). To purify asphaltenes, the precipitation process is followed by Soxhlet extraction. *n*-Pentane is used during Soxhlet extraction until it becomes clear. This requires over 48 h. The maltene fraction can be further separated by column chromatography.

Separation of saturates and resins The SARA column is dry-packed under vibration with various packings, purged with nitrogen and equilibrated with *n*-pentane. The column contains four discretely packed zones with a sequence of H^+ cation exchange resin, OH^- ion exchange resin, clay-coated with ferric chloride, and OH^- ion exchange resin, as illustrated in Figure 4. The maltenes present in the sample are dissolved by the *n*-pentane, placed in the top reservoir and carried into the column. The leaching process is continued by recycling until the eluate is

colourless. Liquid must always be present in the top reservoir. All operations are carried out under nitrogen. The result of the separation is that the gas oils (saturates and aromatics) collect in the bottom flask, whereas the resins remain in the column. The gas oils can be further fractionated into saturates and aromatics on a silica gel column using *n*-hexane as the eluent, with the saturates being eluted first. The cut-off point of elution between saturates and aromatics can be distinguished by UV examination. Under the UV light, the saturates are colourless, whereas the aromatics exhibit a yellow-green colour.

Separation of resins In the analytical SARA separation, the resin content is obtained from the mass balance, by deducting the weights of asphaltenes and gas oils from the original weight of the sample. This method is easy and rapid to quantify the resin content in the bitumen or asphalt sample; however, the fact that resins cannot be collected for further study is a drawback. The resin fraction retained in the SARA column may be semiquantitatively recovered (approximately 90%) by exhaustive elution of the packing with chloroform. For complete recovery of

Figure 5 Stepwise separation of resins. *Acids I are stronger than the corresponding acids II. (Reproduced with modification from Jewell, 1979.)

resins, individual cation/anion columns for stepwise separation are used. This separation process, shown in **Figure 5**, includes cation exchange, HCO_3^- anion exchange, OH^- anion exchange, and clay- FeCl_3 complexation. This scheme provides 10 groups of resins, and this demonstrates the great complexity of petroleum composition.

Separation using the SARA method is a time-consuming process. The extraction time varies with the amount and nature of the sample and especially with the content of asphaltenes and other insolubles pres-

ent. Petroleum residues are commonly extracted overnight, whereas samples of tar sands, shale oils and coal liquids may require 3–4 days.

Centrifugal Preparative Thin-layer Chromatography

Background

Hydrocarbon-type fractions from bitumen, heavy crude and distillation residues can be separated by

TLC. This is a rapid, effective and inexpensive method which has the potential to become the major tool for semi-quantitative analysis of composition of the heavy hydrocarbon mixtures. The application of TLC to the separation of petroleum products has been successfully employed by many investigators (e.g., Lian *et al.*, 1992). A conventional TLC method can differentiate (and characterize) among heavy and residue fractions from petroleum, coal liquids, tar sands, bitumens and asphalts. A preparative, centrifugally accelerated, radial, thin-layer chromatograph (the Chromatotron) is suitable not only for quantitative determination of bitumens and asphalts, but also for the collection of various fractions. It is very important to select the appropriate solvents or solvent mixtures for separation into four fractions. Figure 6 shows the solubility parameters of common solvents in relation to those required to dissolve the various asphalt fractions.

Separation Procedure

One type of centrifugal TLC equipment for analysis of the constituents of hydrocarbon mixtures and especially for determination of the composition of bitumen is illustrated in Figure 7. The preliminary preparation (such as rotor coating, sample preparation and application to the rotor) is important in order to achieve good results. Proper preparation of the sample and the appropriate selection of solvent to

dissolve the sample is very important. Details are discussed in the following sections.

Rotor preparation The glass rotor should meet certain requirements: chemical resistance to solvents and developing reagents, ability to withstand temperatures needed for reaction in the rotor, mechanical strength, thickness uniformity and low cost. Silica gel 60 HF254 + 366 (with a binder) can be used as an adsorbent coated on the rotor as a thin layer. The thickness of the adsorbent layer determines the proper flow rate of mobile phase and solvent volume. Table 2 shows the interrelationships of adsorbent layer thickness, solvent volume and flow rate.

Sample preparation and application The process of adding the sample to the Chromatotron rotor is one of the most important steps to ensure the success of the separation. The solvent used must be highly volatile and nonpolar because solvents with a high boiling point or high polarity are difficult to remove from the adsorbent during sample introduction. Sample injection is performed by means of a pump operated at a low flow rate in order to add a large volume of sample to the rotor and to achieve vaporization of the solvent. Sample introduction as a narrow initial band can enhance the resolution greatly. It is necessary to wait for the solvent to vaporize completely before starting the elution process. If a small

Figure 6 Solubility parameters of common solvents in relation to the values required for dissolution of asphalt fractions. ^a95:5 (v/v); ^btetrahydrofuran; ^cestimated, mixture; ^dcalculated value.

Figure 7 Schematic diagram of the Chromatotron. (Courtesy of Harrison Research.)

amount of solvent is retained in the adsorbent after introduction of the sample, it will adversely affect the separation process due to spreading of the sample in the rotor.

Chromatotron The Chromatotron is a glass rotor coated with a thin layer of adsorbent. The mobile phase and solutions of compounds are introduced to the adsorbent through an inlet, which delivers them close to the centre of the rotor. A motor drives the

rotor at a constant speed, which establishes radial elution of solvent and sample, forming concentric bands of separated substances that move to the edge of the rotor and are channelled by an output tube for collection. The four steps used in the procedure are:

1. Petroleum ether elution of saturated and mono- and diaromatic hydrocarbons.
2. Petroleum ether-ether mixture (80/20, v/v) elution of polyaromatic compounds and resin-1 fraction. This solvent is most suitable for ensuring that the aromatic hydrocarbons form a separate concentric band.
3. Ethyl acetate elution of resin-2 fraction.
4. Tetrahydrofuran elution of asphaltenes.

Table 2 Interrelationships among the thickness of the adsorbent layer, solvent volume and flow rate using the Chromatotron

Thickness of adsorbent layer (mm)	Flow rate (mL min ⁻¹)	Solvent volume (mL)
1	2-4	5
2	6-8	10
4	8-10	20
6	>10	30

The method can be used for both qualitative and quantitative purposes; the complete process is summarized in **Figure 8**. It is very important to determine the cutoff points for the separation process for collecting four high purity fractions. There are two

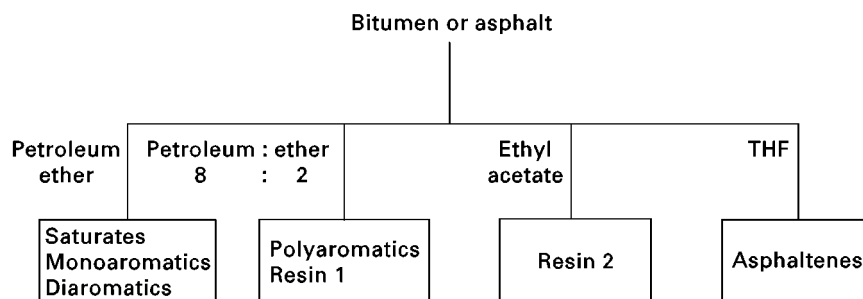

Figure 8 Characterization of bitumen or asphalt by preparative method using the Chromatotron.

methods which can be used to identify the cutoff points:

1. UV examination: this method is useful for estimating the cutoff point between the saturates and aromatics. To identify this point, the rotor can be examined by illumination with UV light at 254 nm. The aromatics will exhibit a yellow-green colour, whereas the saturates are colourless.
2. Spot test: a spot test can be used to identify the cutoff points of saturates, aromatics and resins. Spots obtained using a freshly prepared sulfuric acid-formaldehyde solution (98 + 2, v/v) have the following colours: saturated compounds, colourless; monocyclic aromatics, reddish brown; dicyclic aromatics and polycyclic aromatics, dark green.

Thin-layer Chromatography with Flame Ionization Detection

Background

The fingerprinting of asphalt and its components can be made by TLC-FID much more rapidly and simply than by classical column chromatography and preparative TLC. TLC-FID involves separation of solvent-extractable organics on silica-coated quartz rods called Chromarods into saturates, aromatics and polar component classes combined with semiquantitative detection by automated FID.

Separation

The working principle of a commercially available instrument, the Iatroscan TH-10, designed to scan the adsorbent-coated Chromarods, is illustrated in Figure 9. A set of up to 10 coated rods is mounted on rod holders used for both chromatography and subsequent scanning. The samples to be analysed are dissolved in a solvent and applied near one end of the coated rods, which are then developed using suitable solvents, as in conventional TLC. Thereafter the developing solvent is removed by evaporation, and finally the coated rods are scanned in the FID device. The fractions resolved on each of the Chromarods are

thereby successively vaporized/pyrolysed and the ionizable carbon is detected at the collector electrode. The FID signals from each fraction are amplified and recorded as separate peaks.

In as much as the bitumens comprise a complex mixture of various substances which are impossible to isolate, a compositional analysis technique is generally used whereby a sample is separated into four fractions by performing multistage development with eluting solvents of varying polarities. The solvent elution sequence for asphalt separation is firstly, hexane for separating saturates; secondly, toluene for separating aromatics; and thirdly, dichloromethane-methanol (95/5, v/v) for separating resins. The order of eluted components from the top of the rods is: saturates, aromatics, resins and asphaltenes.

Analysis

TLC-FID is a fast, multiple-analysis method which can be performed simultaneously on 10 samples. The total elapsed time for the analysis is less than 2 h (compared to about 2 days per sample with the SARA procedure). It is, however, destructive and does not yield fractions for further examination.

Linearity of response versus concentration is important in obtaining quantitative results. The sample size, the flow rate of hydrogen fed to the FID and the speed of scanning all have an effect on the linearity of response versus concentration, baseline stability of the FID signal and reproducibility of response values.

Silica Gel and Ion Exchange Chromatography – Separation of Polar Fractions

Background

The separation and study of polar compounds in crude oil and bitumens is of considerable importance in the fields of petroleum recovery and processing. Numerous methods for separation of polar compounds

Figure 9 Construction of a coated-rod TLC scanner, latroscan TH-10 Mk III. (Modified from Mukherjee, 1991.)

from crude oil and bitumens have been developed. Among these, the most widely used is the method developed by the Bureau of Mines and American Petroleum Institute. The acid and base fractions of heavy petroleum distillates or residues are isolated by ion exchange chromatography, the neutral nitrogen compounds by complexation chromatography on ferric chloride and saturates, and mono-, di- and polyaromatics by adsorption chromatography on activated alumina or on a combined alumina-silica gel column. The definition of acids or bases by ion exchange methods is based on the hydrogen donating or accepting tendency of the molecules. In as much as many polar compounds are amphoteric, their definition as acids or bases depends on the analytical sequence employed. Although this method is rather complex and tedious, it is used to separate the polar fractions from crude oil and bitumens.

Separation Procedure

There are two stages in the separation: firstly, silica gel chromatography and secondly, ion exchange

chromatography. The first stage separates the crude oil or bitumen into four fractions (I-IV: **Figure 10**). The polar fraction obtained from the first stage is further split into subfractions by the second-stage chromatography.

Silica gel chromatography Fractionation of crude oil or bitumen is carried out by solvents with increasing polarity through a column using Baker reagent grade, 60-200 mesh silica gel. The silica gel is thermally activated before use. The sample (10-20 g) is dissolved in 200 mL tetrahydrofuran (THF) and then filtered. The volumetric ratio of the sample to the adsorbent is about 1:35. The columns are eluted with *n*-hexane, toluene, 4:1 (v/v) toluene-methanol and 2:1 (v/v) toluene-methanol, to obtain fractions I, II, III and IV, respectively. Figure 10 shows the overall separation scheme. All samples must be evaporated to a constant weight by (rotary) evaporation and using a vacuum oven. Recovery of fraction IV is generally lower than 5% and, therefore, this fraction has not been considered for further study. The most polar

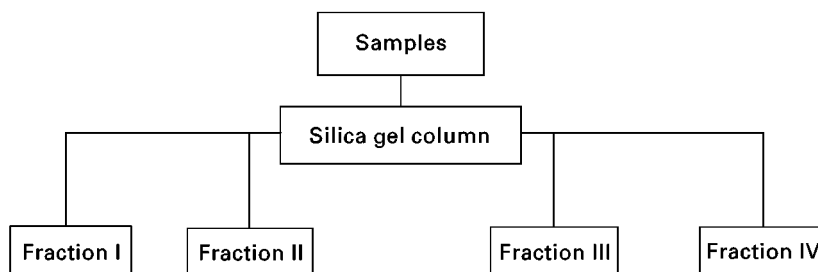

Figure 10 Solvent fractionation scheme using a silica gel column for crude oil and shale oil.

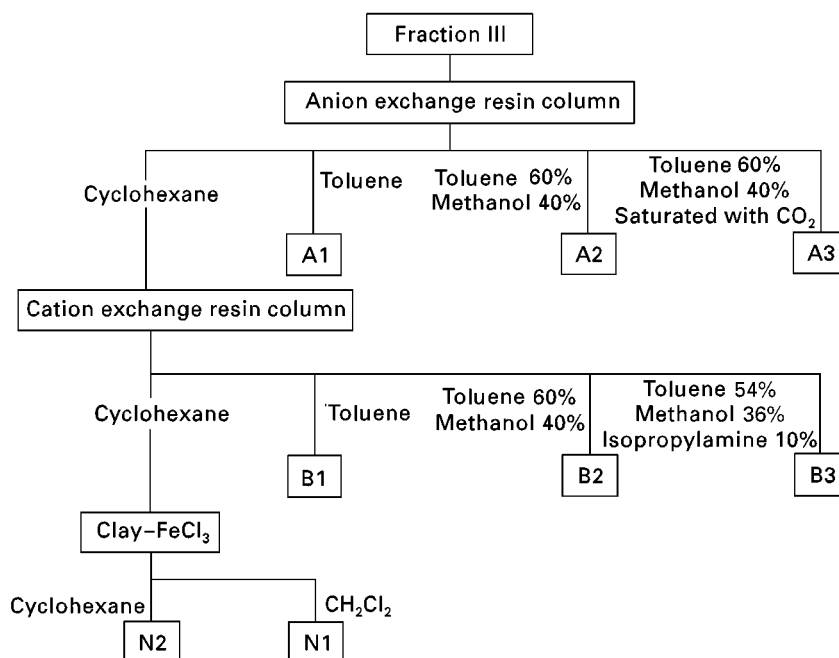

Figure 11 Separation of fraction III (see Figure 10) to subfractions by ion exchange chromatography: A, acid; B, base; and N, neutral.

groups are present in fraction III because of the high interfacial tension compared with those for fractions I and II. Fraction III is further fractionated by ion exchange chromatography.

Ion exchange chromatography The polar material (fraction III) obtained using the silica gel column is mixed with cyclohexane. There are three further stages of separation: anion exchange, cation exchange and clay-FeCl₃ complexation. In order to obtain acidic fractions from the polar material, a strongly basic anion exchange resin is used and an eluting scheme is employed, based on increasing polarity of the solvent. This scheme includes four elution steps: cyclohexane; toluene; a 3:2 mixture of toluene-methanol; and a 3:2 mixture of toluene-methanol saturated with CO₂. The first fraction eluted by cyclohexane from the anion exchange resin is further fractionated by passing it through a strongly acidic cation exchange resin. The same elution scheme as in the first elution step is used, with a slight modification for the cation exchange elution in that the fourth step uses a 5.4: 3.6:1.0 mixture of toluene-methanol-isopropylamine. Three basic fractions result from these fractionations.

A column packed with clay-FeCl₃ is employed to separate further the material obtained from the cyclohexane elution in the second stage. The solvents used to obtain the neutral fractions are cyclohexane and dichloromethane. The volumetric ratio of sample to adsorbent is around 1:10 for the three adsorbents

used. Two neutral fractions can be obtained at this last stage of separation process. A detailed diagram of the scheme is given in Figure 11.

Conclusion

The SARA separation method is at present the most comprehensive and most widely used method for the study of heavy oil fractions. Despite its shortcomings (tedious, time-consuming and possible losses), it can be viewed as a standard by which other methods should be evaluated. Preparative, centrifugal, TLC with the Chromatotron is capable of isolating crude oil and bitumen in the amounts required for further identification by other instrumental techniques.

TLC-FID has a great potential of becoming a standard method for quantitative evaluation of crude oil and bitumen. It is rapid, accurate, requires only small samples and does not involve tedious procedures in comparison to the SARA method. Solvent fractionation using silica gel rods simply separates crude oil and bitumen into four fractions. With automatic instrumentation, the method can be used routinely for industrial purposes. The combination, of fractionation by solvents and ion exchange followed by complexation, is a good method for studying the composition of crude oil and bitumen. Ion exchange processes rely on the great selectivity for acidic and basic components in the crude oil. The complexation process enables the neutral nitrogen compounds to be separated. This scheme provides 10

resin fractions, which demonstrates the great complexity of crude oil composition.

The choice of a procedure primarily depends on the information required. Combining different separation steps and/or short-cuts to achieve a specific purpose is possible.

CARBAMATE INSECTICIDES IN FOODSTUFFS: CHROMATOGRAPHY AND IMMUNOASSAY

G. S. Nunes, Federal University of Maranhão/UFMA, São Luís-Ma, Brazil

D. Barceló, CID/CSIC, Barcelona, Spain

Introduction

Pesticides have received special attention over the years, due mainly to the problems of environmental and food contamination. Analytical methods for determining pesticide residues have their main application in the control of food for human consumption,

especially in the control of fruit and vegetables produced using direct applications of pesticides. Moreover, the determination of pesticide residues in food is fundamental in monitoring and regulatory programmes. Pesticide residue levels higher than the maximum residue level (MRL) are monitored through two different but complementary approaches: regulatory monitoring focusing on raw agricultural commodities that measure the levels in individual lots for compliance with legal tolerances, and total diet study, in which dietary intakes of pesticides are determined by analysis of fruit and vegetables.

Carbamates constitute a family of pesticides registered for use on several crops in South America, Europe and the USA. Their use for pest control has progressively increased in recent years, along with organophosphates (OPs), as alternatives to organochlorine (OC) insecticides. Owing to their broad spectrum of biological activity, carbamates can be used as insecticides, miticides, fungicides, nematocides and molluscicides. **Table 1** shows the structures of the most extensively used carbamates, including some *N*-methylcarbamate (NMC) insecticides. Carbamate residues are of concern because of the acute toxicity of some compounds – aldicarb and carbofuran exhibit an LD₅₀ (the dose of a compound that causes death in 50% of the organisms to which it has been administered) in rats of 1 and 8 mg kg⁻¹, respectively. Some carbamate residues are suspected carcinogens and mutagens. Such insecticides act as inhibitors of the acetylcholinesterase enzymes, and a number of adverse effects have been reported in the literature.

Several analytical methods have been proposed for the separation and quantification of carbamate residues in food samples. The carbamate pesticides are thermally labile and not readily amenable to gas chromatography (GC), making the use of the liquid chromatographic (LC) techniques preferable. In general, the time and expenses involved in classical analytical methods (i.e. sampling, sample preparation and laboratory analysis) have substantially limited the number of samples that can be analysed in food research and surveys. In addition, the quantity of chemicals and toxic solvents that are used sometimes offer a risk factor considerably greater than that of the pesticide residue to be determined. These disadvantages have emphasized the need for developing fast, easy, robust, sensitive and cost-effective methods capable of being used in the field. Instrumental techniques that combine these characteristics are slowly starting to appear in pesticide residue analysis. They include the immunoassay (IA) techniques, immunoaffinity chromatography and electrochemical/optical biosensors. To avoid the general drawbacks of the classical methods, significant developments have

taken place in extraction/clean-up procedures, and in the final determination of pesticide residues in foodstuffs.

This article examines recent progress, focusing primarily on simplified and miniaturized analytical methods for determining carbamate insecticides in foodstuffs, including fast and simple extraction/clean up strategies, and the use of IA techniques for detection prior to laboratory analysis.

Chromatographic Methods for Carbamate Analysis

LC Methods

Standard LC methods for carbamate determination based on Krause's method generally consist of reversed-phase HPLC with gradient elution followed by two post-column reactions to yield fluorescent species (**Figure 1**). The carbamates are hydrolysed with an alkaline solution (usually sodium hydroxide) to a methylamine that is sequentially derivatized in the presence of *o*-phthaldehyde (OPA) and mercaptoethanol (MERC) to create the fluorescent product. Two high pressure pumps are used to introduce the post-column reagents. To separate the main NMCs and their metabolites, a cycle time of 45–60 min is required. Limits of detection (LODs) in water analysis are in the range of 1 to 4 ng, which is equivalent to 2.5 to 10 p.p.b. in the water injected. However, if a preconcentration step is carried out before chromatographic separation, the LOD value is lower.

The sensitivity and selectivity of Krause's method have allowed its use for the determination of residues of NMCs in fruits and vegetables with great accuracy. Unfortunately, such methods involves extraction with methanol, and large amounts of sample and solvent are used. The clean-up, starting with successive liquid–liquid partition (LLP) steps, and finishing with elution of the target compounds on a Celite®/charcoal adsorbent column, is mainly responsible for the slowness and tediousness of the method, making the analysis of a large number of samples impractical. Usually, it is satisfactorily used as a reference method in collaborative studies and also to carry out validation of new methods. Different procedures for clean-up of crop extracts by employing either glass adsorbent columns and commercially available solid-phase extraction (SPE) cartridges have been compared and a specific solid-phase elution protocol employing a solvent polarity gradient proposed. A schematic outline of the method is illustrated in **Figure 2**. The extraction is carried out with methanol, and a LLP step is only necessary if a UV detector is to be used. In most cases, recoveries of the more polar compounds

Table 1 Carbamates commonly used in crop protection and some of their breakdown products

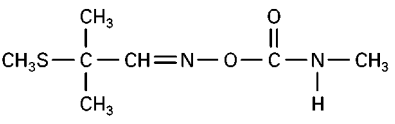

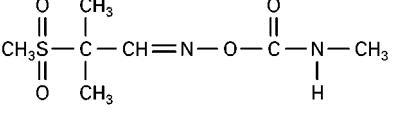

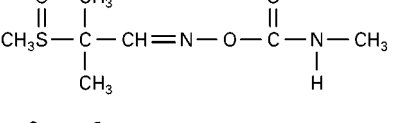

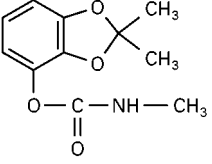

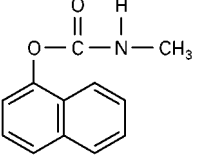

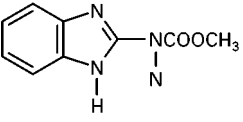

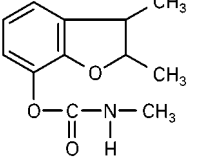

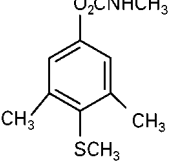

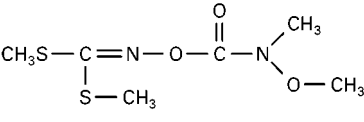

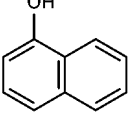

Compound name	Chemical structure	Class	IUPAC name
Aldicarb		Insecticide	2-Methyl-2-(methylthio)propionaldehyde <i>o</i> -methylcarbamoyloxime
Aldicarb sulfone		Insecticide (metabolite of aldicarb)	2-Methyl-2-(methylsulfonyl)propanal <i>o</i> -[(methylamino)carbonyl]-oxime
Aldicarb sulfoxide		Insecticide (metabolite of aldicarb)	2-Methyl-2-(methylsulfinyl)propanal <i>o</i> -[(methylamino)carbonyl]-oxime
Bendiocarb		Insecticide	2,3-Isopropylidenedioxyphe-nyl methylcarbamate
Carbaryl		Insecticide	1-Naphthyl methylcarbamate
Carbendazim		Insecticide	2-Methyl benzimidazol-2-ylcarbamate
Carbofuran		Insecticide	2,3-Dihydro-2,2-dimethylbenzofuran-7-yl-methylcarbamate
Methiocarb		Insecticide, acaricide, molluscicide	4-Methylthio-3,5-xylyl methylcarbamate
Methomyl		Insecticide	<i>S</i> -Methyl <i>N</i> -(methylcarbamoyloxy) thioacetimidate
1-Naphthol		Insecticide (metabolite of carbaryl)	1-Naphthalenol

Table 1 Continued

Compound Name	Chemical structure	Class	IUPAC name
Oxamyl	$ \begin{array}{c} \text{O} \quad \quad \text{O} \quad \text{H} \\ \parallel \quad \quad \parallel \quad \\ (\text{CH}_3)_2\text{N}-\text{C}-\text{C}=\text{N}-\text{O}-\text{C}-\text{N}-\text{CH}_3 \\ \\ \text{SCH}_3 \end{array} $	Insecticide, nematocide, acaricide	<i>N,N</i> -Dimethyl-2-methylcarbamoyloxime-2-(methylthio)acetamide
Pirimicarb		Insecticide	2-Dimethylamine-5,6-dimethylpyrimidine-4-dimethylcarbamate
Propoxur		Insecticide	2-Isopropoxyphenyl- <i>N</i> -methylcarbamate

are higher if the partitioning step is omitted and fluorimetric detection is employed.

A series of tests to assess the feasibility of using activated carbon membranes in the clean-up of vegetables (green peppers) for the analysis of NMC pesticides by HPLC with post-column derivatization and fluorescence detection have been carried out. These tests showed that the membranes were effective in retaining sample interferences in both offline (with a 22 cm diameter activated carbon membrane) and online (extract injected directly in the HPLC system) methods. Solid-phase extraction with bonded-silica adsorbents, including octyl (C_8), ethyl (C_2), octadecyl (C_{18}) and cyclohexyl (CH), has also been successfully developed as an alternative to LLP clean-up. Elution patterns and recovery from various adsorbent materials were determined for 17 OPs, nine carbamates and

three other pesticides in a sample matrix of rice grain. The method performance was comparable to conventional clean-up procedures.

Following the general tendency toward miniaturization, a new method for NMC determination in fruits and vegetables has been proposed. This method eliminates the need for delivery pumps to introduce the hydrolysis/derivatization reagents, since they are already present in the mobile phase. For this purpose, a Kromasil-100 C_{18} column (which tolerates basic conditions) and a borate buffer mobile phase were chosen. A simplified LC-fluorescence (FS) method for the determination of traces of carbamates in grains, fruits and vegetables has been described. Here, the sample size and solvent volumes were considerably reduced, and a clean-up on aminopropyl-bonded Sep Pak® cartridge was performed in order to separate the target compounds from the coextractives. Recovery of the pesticides and limits of detection in different food matrices varied from 60 to 103% and from 1 to 4 ppb. A complete analytical methodology for the determination of some NMCs in vegetable, fruit and feed crop samples has been developed in which the pesticides are extracted, cleaned on an aminopropyl-bonded SPE column, and then determined by LC-FS.

Depending on the detection technique, not only the method selectivity, but also the method sensitivity, can be changed considerably. For example, by using LC with UV detection, the presence of coextractives can severely limit the analyte determination, resulting in poor method sensitivity when analysing real samples compared with standard solutions. Despite this, and considering that the maximum residue levels for foodstuffs are higher than those for water samples,

Figure 1 Liquid chromatography system with post-column reactions and fluorimetric detection for determination of *N*-methylcarbamate pesticides.

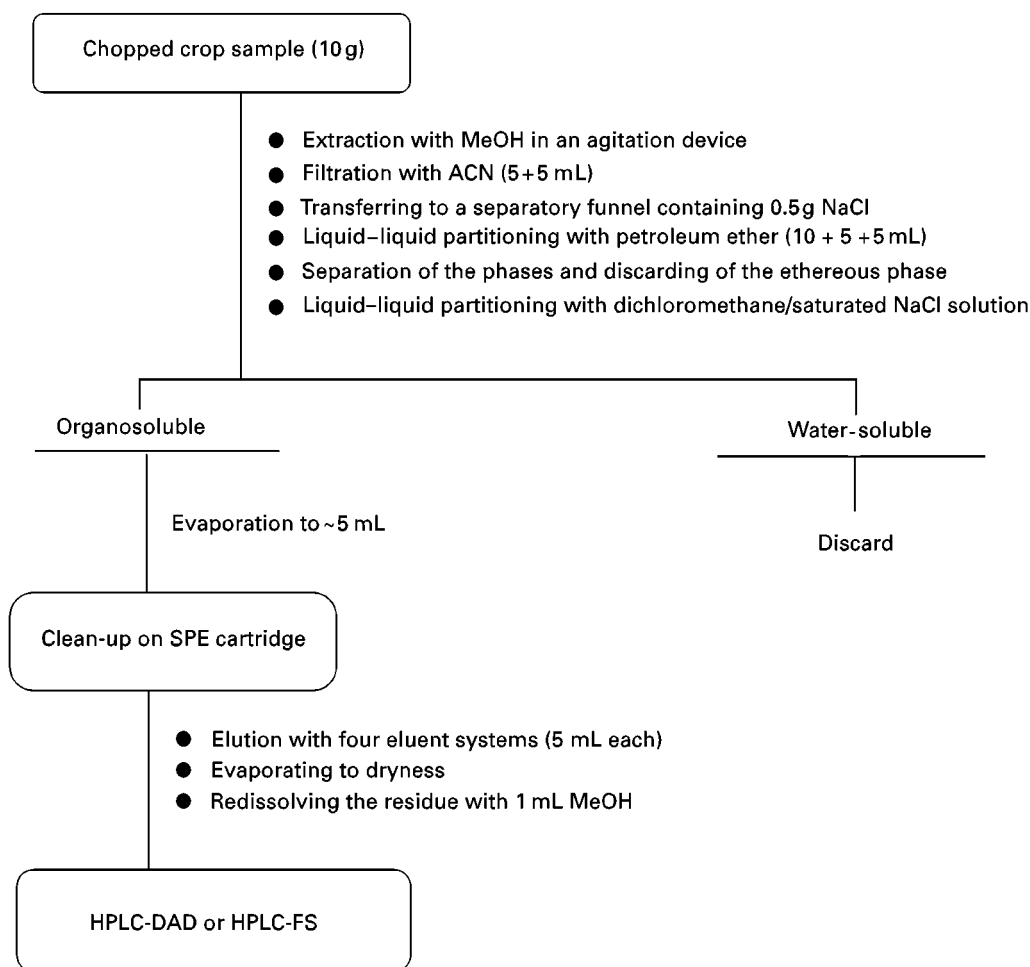

Figure 2 Block diagram of a scheme for extract preparation for HPLC analysis *N*-methylcarbamate pesticides in fruit and vegetables. If fluorimetric detection is performed, the LLP step can be omitted. Elution through an SPE column was carried out according to the method described by Nunes GS, Ribeiro ML, Polese L and Barceló D (1998) Comparison of different clean up procedures for the determination of *N*-methylcarbamate insecticides in vegetable matrices by high-performance liquid chromatography with UV detection. *Journal of Chromatography* 795: 43–51.

a simple and rapid method has been proposed to analyse eight carbamate insecticides and 10 of their main metabolites in apples, pears and lettuce. The clean-up procedure is based on that of the De Kok method, which uses solid-phase cartridges, and the amounts of solvents and sample are substantially reduced. It was found that matrix interferences could be minimized by diluting the final extract, but the method sensitivity is also reduced.

GC Methods

The relationship between the mode of detection and the required extraction procedure for this mode has resulted in the emergence of numerous sample preparation procedures. Using GC-mass spectrometry (MS) and LC-FS techniques, the extraction of 199 pesticides from fruits and vegetables with acetonitrile, and removal of the coextractives with a minia-

ture charcoal-Celite clean-up column have been carried out. Good recovery data obtained by spiking pears, carrots and bananas at the 0.1–0.5 p.p.m. demonstrated the excellent performance of this method.

Various types of detectors have been evaluated for the analysis for the carbamate insecticides by GC. Among these, the nitrogen-phosphorus detector (NPD), the flame photometric detector (FPD) with either a phosphorus or sulfur filter, the electron-capture detector (ECD) and the mass spectrometric detector (MS), either in electron impact mode (EI) or in positive chemical ionization (PCI) mode, have been tested. Sensitivity, linearity and selectivity of the different detectors have been detailed and application to real samples, including foodstuffs, has also been presented. Although the thermolability of the carbamates is considered the major limitation as regards to the use of GC techniques, it has been shown that

thermal degradation of some carbamates and metabolites does not occur under certain conditions, as was demonstrated by the fragmentation patterns of the studied compounds. GC-NPD methods for the monitoring of residues of some carbamates in real samples have been also described. A comparison has been made of GC and LC techniques for the analysis of the most popular (in terms of amount produced and applied) pesticide classes, such as carbamates, phenylureas, triazines, phenoxy acid herbicides and chlorinated phenols. Sample concentration and detection have been discussed in relation to their influence on the performance of the particular separation technique. GC methods, when applicable, have the advantages of greater separation efficiency, higher speed of analysis and the availability of a wide range of highly sensitive detectors. On the other hand, LC is often the choice when polar, nonvolatile and/or thermolabile compounds need to be analysed, as it is in the case of carbamates.

Supercritical Fluid Chromatography/Extraction

Supercritical fluid chromatography (SFC) is a technique that in many ways is a hybrid of GC and HPLC. It is recognized as a valuable technique for the analysis of thermally labile compounds such as carbamates. A few applications have been reported for SFC in the field of pesticide determination in food. The versatility in separation, the possibility of using different detectors (LC or GC detectors), and the prospect of directly coupling with supercritical fluid extraction (SFE), make this analytical technique very attractive. SFE using CO₂ has been examined for separating carbamates from interfering coextractives prior to analysis either by LC-MS or by GC with ion trap mass spectrometry (ITMS) detection. Pre-extraction of ground meat with acetonitrile before SFE left behind over 99% of the fat and fibre. SFE of the acetonitrile extracts with pelletized diatomaceous earth further reduced the amount of coextractives 10-fold, removing the interferences that would have appeared in the fluorescence mode.

Simplification of Multiresidue Methods

Official laboratories that investigate and analyse pesticide residues usually utilize the established multiresidue methods (MRM) of analysis. One of the most commonly used MRM for pesticide analysis in fruit and vegetables samples is the AOAC (Association of Official Analytical Chemists) method. It involves an aqueous acetone extraction and laborious clean-up

employing LLP procedures using organic solvent of limited water capacity, to achieve the removal of the coextractives present in the sample extract and/or solid-phase clean-up with silica or Florisil. Finally, analyte determination is performed by GC or HPLC with selective detectors.

More than 300 pesticides and pesticide-related compounds can be determined by the well-known MRMs described in the official literature, such as the AOAC method, the German MRM S19 (Deutsche Forschungsgemeinschaft, DFG), and the method adopted by the National Food Administration of Sweden. They all have several disadvantages, such as their inefficiency as screening methods, since they are too time-consuming and labour-intensive, the large amount of solvents used, and, in addition, newly developed groups of pesticides are becoming more polar and/or thermodegradable, making difficult their analysis by conventional chromatographic techniques.

During the past two decades, research has gone in the direction of reduction of organic solvent toxicity, elimination of the partition step and elimination of the column clean-up. A rapid and efficient multiresidue extraction procedure has been reported using ethyl acetate and sodium sulfate, followed by gel permeation chromatography (GPC) on an SX-3 column. Its effectiveness to analyse OC and OP insecticides was confirmed. Several other methods based on it have arisen using specific detectors that have decreased the number of interfering chromatographic peaks.

LC-MS Techniques

Confirmation of the presence of carbamates in real samples has been performed by HPLC-MS with various interfaces, but in general most of these studies have been performed with standard solutions. **Table 2** summarizes the development of LC-MS techniques for the analysis of different pesticides, including carbamate insecticides. Up to the present, few food analysis applications have been reported. Atmospheric pressure chemical ionization (APCI) techniques for the mass spectral analysis of several NMCs have been evaluated and the results compared with those obtained using ionspray (ISP) and thermospray (TSP) interfaces. The results were also compared with EI ionization and methane CI spectra obtained with a particle beam (PB) interface. These methods were applied to the confirmatory analysis of three representative carbamate pesticides, spiked at the 0.1 ppm level in green peppers.

Multiresidue confirmations of pesticides from different classes using APCI techniques have also been performed. It was observed that the fragmentation of the carbamates studied was highly voltage-dependent. An increase in the potential of the sampling

Table 2 MS interfaces most commonly used for LC analysis of pesticides, including carbamate insecticides

<i>Spectrometry interface</i>	<i>Pesticides studied</i>	<i>Sample type</i>	<i>LOD (ng)</i>
APCI, ISP, TSP and CI	NMCs	Aqueous solutions Green peppers Ground water	— Full-scan mode: 0.8–10 SIM mode: 0.01–1
APCI (in positive- and negative-ion modes), TSP, and PB-MS	17 pesticides in five chemical classes (triazines, phenylureas, carbamates, organophosphorus and miscellaneous)		
TSP	Anilides, carbamates, <i>N</i> -heterocyclic, organophosphorus, and phenylureas)	Aqueous solutions	—
TSP (with online and offline SPE procedures)	Nitrogen- and phosphorus-containing pesticides	Aqueous solutions	SIM mode: 0.04–0.6
TSP	3 <i>N</i> -methylcarbamates, 3 <i>N</i> -methylcarbamoyloximes, 2 substituted urea pesticides, and 1 ester of a substituted carbamic acid	Aqueous solutions	—
TSP (with either filament- and discharge-assisted ionization modes)	19 carbamates and 12 of their known degradation products	Aqueous solutions	—
TSP	16 carbamates from four chemical subclasses (oxime-NMCs, aryl-NMCs, <i>N</i> -phenylcarbamates and methyl esters of substituted carbamic acids)	Aqueous solutions	—
FIA-PB-PCI	14 carbamates	Aqueous solutions	—
FIA-PB-EII-CI (with either negative- and positive-ion modes)	33 carbamates and 14 of their degradation products	Surface water	—

cone strongly affected the formation of diagnostic daughter ions. The dependence of the ion abundances in the TSP mass spectra of several pesticides has been studied with regard to the vaporizer and the gas-phase temperatures and under collision-activated dissociation conditions. Fragmentation pathways under certain experimental conditions were investigated for some of the carbamate pesticides. Both vaporizer and source jet temperatures were monitored. APCI, ESP, fast-atom bombardment, Cf-252 plasma desorption and collision-activated dissociation spectra were then performed for the pesticides to confirm proposed pathways and to gain additional information.

Through an interlaboratory study involving nine laboratories, it was concluded that, in TSP-LC-MS systems, the thermospray tip temperature plays a major role in adduct formation and ion fragmentation of thermally labile carbamate pesticides. As a result, this temperature needs to be carefully controlled. This effect has been confirmed by investigating the influence of three LC eluent additives (ammonium acetate, ammonium formate and nicotinic acid) and the vaporizer temperature on ion formation. The performances of different thermospray interfaces (which exhibit wide differences in source geometry) used in

carbamate analysis have also been compared, and the so-called suppression effects on the ion formation have been studied in coeluted compounds. Thermally labile carbamates gave unsatisfactory results with regard to spectral compatibility between the interfaces. These differences are due to thermally assisted hydrolysis reactions that occur in the various vaporizer designs. Different approaches using desorption chemical ionization (DCI) and flow injection (FIA)-particle beam (PB)-ammonia PCI-MS were further evaluated. The mass spectra using FIA-PB-PCI-MS exhibit higher relative abundances for fragment ions, and the ion intensities are strongly dependent on the ion source pressure. Another study, employing EI ionization and ammonia/methane with positive/negative chemical ionization, has shown ammonia to be the best reagent gas. Using ammonia gave less fragmentation and better quantitative results than methane for the analysis of 33 carbamates and 14 of their degradation products.

LC-APCI-MS and LC-post-column fluorimetry for the determination of carbamates in foodstuffs were compared. It was observed that, despite its great potential in detection and confirmation, in general LC-APCI-MS is less sensitive for quantitation

purposes, which agrees with previous reports. The feasibility of using reversed-phase LC-MS with an electrospray interface for measuring traces of NMC insecticides in 10 different types of fruit and vegetables has been evaluated. Extraction with methanol, followed by clean-up on a Carbograph 1 extraction cartridge, provided an average recovery higher than 80% for all compounds. It was noticed that changing from methanol to acetonitrile as the organic modifier resulted in a significant decrease in ion signal for the carbamates. The presence of coextractives derived from the crop samples in the electrosprayed solution did not interfere significantly with the ionization process of the compounds studied. The photochemical behaviour of pesticides in a photolysis reactor coupled online with an LC-ESP-MS system has been investigated this system has been used successfully to trace confirmatory analysis of carbamates in foodstuffs.

Recently an analytical method for confirmation of aldicarb and its metabolites in fruit and vegetable samples has been optimized. Aldicarb is one of the NMCs most commonly used for insect control in tropical countries in different agricultural fields. Figure 3 illustrates schematically the metabolic pathway of aldicarb under environmental conditions, and shows the formation of the mass fragments used to identify the parent and metabolic compounds. Initial metabolic attack is rapid and complete oxidative conversion to aldicarb sulfoxide is followed by a much

slower oxidation to the sulfone. It is interesting to consider the rapid degradation of aldicarb after its application, because in some cases the parent compound is not present in the studied matrix. Since that the toxicity could be effectively more acute if the metabolites were present in more elevated concentrations, their confirmation in real samples by LC-MS is of crucial importance. Such compounds have been analysed by LC-APCI-MS using the selected ion monitoring (SIM) mode based on five channels. Figure 4 shows a typical total ion chromatogram and the five selected ions used to identify the compounds in orange extracts. Here, the fragmentation was assisted by the addition of ammonium formate in the mobile phase (acetonitrile/water) and ion adducts did not appear in the mass spectra, resulting in a sensitive method free from interferences.

Thin Layer Chromatography Methods

Thin-layer chromatography (TLC) is used for the qualitative and quantitative analysis of a wide variety of compounds, including pesticides. Among the carbamate insecticides analysed by TLC can be found those most commonly used in crop protection, such as carbaryl, carbofuran, methomyl, bendiocarb, propoxur, aldicarb and carbendazim. Since the 1980s, only a few papers concerning carbamate analysis by TLC have been published. Thin-layer chromatographic procedures have been developed for the separation of several carbamates, such as

Figure 3 Metabolic pathway of aldicarb to its degradation products under environmental conditions, and mass fragments used for the LC-MS confirmation of the compounds.

Figure 4 Mass spectra for (1) aldicarb sulfoxide (2), aldicarb sulfone and (3) aldicarb present in a spiked orange extract. Peak confirmation by SIM mode of five selected channels on the total ion chromatogram (TIC). Final extract 20-fold concentrated (see sample preparation in Figure 2). Chromatographic separation of the compounds was carried out using a C_{18} RP-LC column and a water/acetonitrile mixture, both containing 0.1% ammonium formate as mobile phase.

carbaryl, bendiocarb, carbofuran, 2-isopropyl-phenyl-*N*-methylcarbamate (MIPC) and 2-*sec*-butyl-*N*-methylcarbamate (BPMC). Suitable schemes using plates coated with silica gel containing 1% zinc acetate as support, and benzene/ethyl acetate (50:10) as solvent have been developed for carbamate analysis in various matrices, such as aqueous biological fluids and food samples, mainly fruit juices. Residues of carbofuran and its two metabolites have been extracted with HCl, partitioned into CH_2Cl_2 , chromatographed on silica gel and detected with KOH-*p*-nitrobenzenediazonium fluoroborate. Sequential TLC has been used for the detection and determination of carbaryl in water samples. More recently, the chromatographic behaviour of carbamate pesticides and related compounds has been examined on thin layers of alumina, barium, sulfate, calcium carbonate, calcium phosphate, calcium sulfate, cellulose and silica Gel G[®].

Immunoassay (IA) Methods for Carbamate Determination

In the last few years, the number of enzyme-linked immunosorbent assay (ELISA) methods for the determination of pesticides has increased, but there is still a lack of IA methods for pesticide residue determination in food and crop samples. IA techniques can provide complementary and/or alternative approaches in reducing the use of expensive equipment

and analysis time while still maintaining reliability and sensitivity. Moreover, IA can be used as a screening method in order to detect food contamination. The relatively short analysis time allows for the screening of a large number of samples which is a major advantage.

IA has been shown to have potential as a screening method for the detection of pesticides in food samples. A rapid bioluminescence method was used for screening several OP and NMC insecticides in processed baby food. Among the 155 samples tested, there were 23 suspected positives (14.2%) that were further analysed by HPLC; this resulted in confirmation of the presence of carbaryl in 18 of the samples.

The utility and applicability of an analytical method depends in great part on the absence of matrix interferences. In this regard, ELISA is not different from other detection techniques, and the sample preparation prior to analysis is still a critical point for pesticide residue determination by IA methods. A competitive ELISA has been developed for quantification of methyl 2-benzimidazolecarbamate in fruit juices. Matrix effects are minimized by diluting the samples before IA. Rapid methods based on water or acetonitrile extraction have been evaluated for screening carbofuran and aldicarb sulfone in mean and liver using commercial ELISA kits. The final extracts are diluted in order to eliminate the effect of the solvent, which is more pronounced than the natural compound effects in some cases. Attempts have been made to minimize the matrix and organic solvent effects in ELISA for carbaryl by diluting the crop extracts in the assay buffer, but it was observed that the effect of the solvent residue in the diluted extracts on the assay was still higher than the matrix effect. The direct application of IA to vegetable/fruit juices diluted in the assay buffer is possible, without large losses in the method sensitivity. As an example, **Figure 5** shows some calibration curves for carbaryl in assay buffer and in lemon juices diluted in assay buffer. In this case the absence of matrix effect, after sample dilution and pH adjustment, indicates good IA performance. Unfortunately, in most cases the recoveries of IA-based methods have proved to be lower than those of methods that do not employ any prior sample treatment.

Different experimental approaches to ELISA quantification of NMC insecticides in fruit juices, without any sample pre-treatment other than dilution, have also been developed. For carbaryl and carbofuran residue determination in fruit juices, high affinity monoclonal antibodies (MABs) have been used. Offline SFE and ELISA have been used for the determination of nine pesticides, including four carbamates, in foodstuffs consisting of baby food and Food and

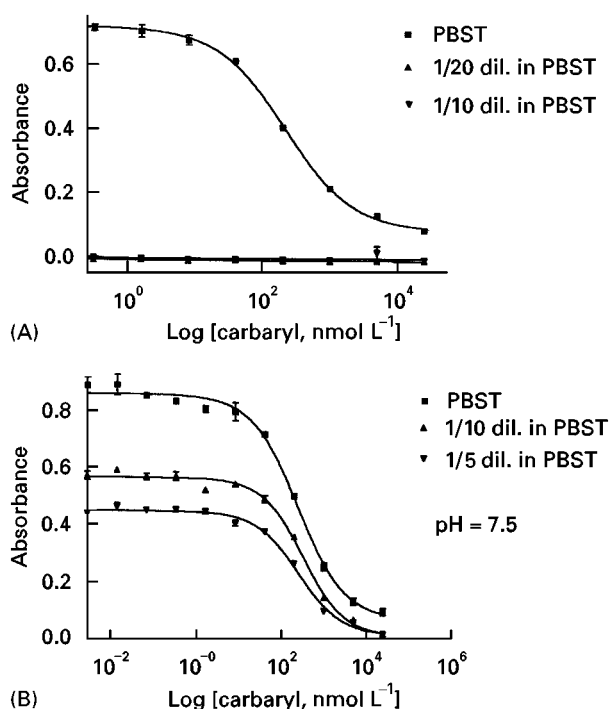

Figure 5 Matrix effect of lemon juice on the enzyme-linked immunosorbent assay (ELISA) for carbaryl analysis. Calibration curves were constructed with PBST buffer and PBST-diluted lemon juices. (A) Natural pH of the diluted samples; (B) pH adjusted with an alkaline solution. PBST, (Reproduced with permission from Nunes GS (1999) Analysis of *N*-methylcarbamate insecticides by chromatographic techniques, immunoassay (ELISA) and amperometric biosensors. Institute of Chemistry IUNESP, Anaraquara, São Paulo, 230 pp [doctorate thesis].

Drug Administration (FDA) Total Diet Study (TDS) samples. The benefits of SFE-ELISA included replacement of harmful organic extraction solvents, rapid extractions with a relatively inexpensive extractant, and a reduced number of steps in the determination of the target compounds.

In contrast to conventional chromatographic techniques for pesticide analysis in foods, IA methods have not yet been extensively characterized. The validation of the proposed ELISA against another validated method has been the primary objective in only a few published papers. As for any analytical method, quality control and assessment of material and equipment stability are required. In addition, IA evaluation involves defining working ranges, sensitivity, precision, accuracy, linearity, specificity and matrix effects.

Immunoaffinity Chromatography

Immunoaffinity chromatography (IC) has been widely used for the determination of various analytes in the medical field; however, the use of antibodies immobilized on an appropriate support to pre-concentrate pesticides from environmental samples is only

a recent development. In the analysis of pesticides in food matrices, the use of IC is still more limited. IC is based on the highly selective interaction of antigens with their antibodies, which are immobilized on a support material called an immunosorbent. The production of antibodies against pesticides is based on the conjugation of hapten to a large immunogenic carrier molecule (typically bovine serum albumin or keyhole limpet haemocyanin), and subsequently the complex is injected into a suitable vertebrate (rabbit, mouse, rat, sheep). Since antibody-antigen interactions occur over short distances, steric effects are involved in the coupling reaction. These steric effects are what make antibody-antigen interactions so selective, and only the antigen that produced the immune response, or very closely related molecules, will be able to bind to the antibody. Thus, theoretically, when the sample is run through the immunosorbent the analytes are selectively retained and subsequently eluted free of the coextratives (Figure 6). Once the analytes have been separated from interferences, they can be determined by conventional chromatographic techniques. The use of IC as a separation tool before pesticide analysis is thus extremely attractive.

Among the carbamate pesticides, only carbofuran has been separated from natural components of crop samples by IC and a highly sensitive online IC with coupled-column LC-MS was used to analyse some fruit and vegetable samples.

Current Trends and Conclusions

A tremendous amount of work has been done and much more is under way in the field of pesticide analysis in food samples. In the chromatographic field several new techniques for pesticide analysis, such as immunoaffinity chromatography and LC-MS with various interfaces, have appeared. These have undoubtedly contributed to increased separation efficiency and improved sensitivity. It is expected that the bioanalytical techniques for pesticide analysis will become a common analytical alternative because of their demonstrated advantages, especially in the analysis of carbamates in food samples. The capacity that these compounds show in inhibiting a certain class of enzymes (the cholinesterases) must be further explored. Development of approaches based on the coupling of the chromatographic separation with biodection systems is a promising alternative.

Sample handling is the bottleneck in the analysis of carbamate insecticides in foodstuffs, since in many cases a complex clean-up step is needed before chromatographic separation. The use of biological techniques, such as immunoassays and biosensors,

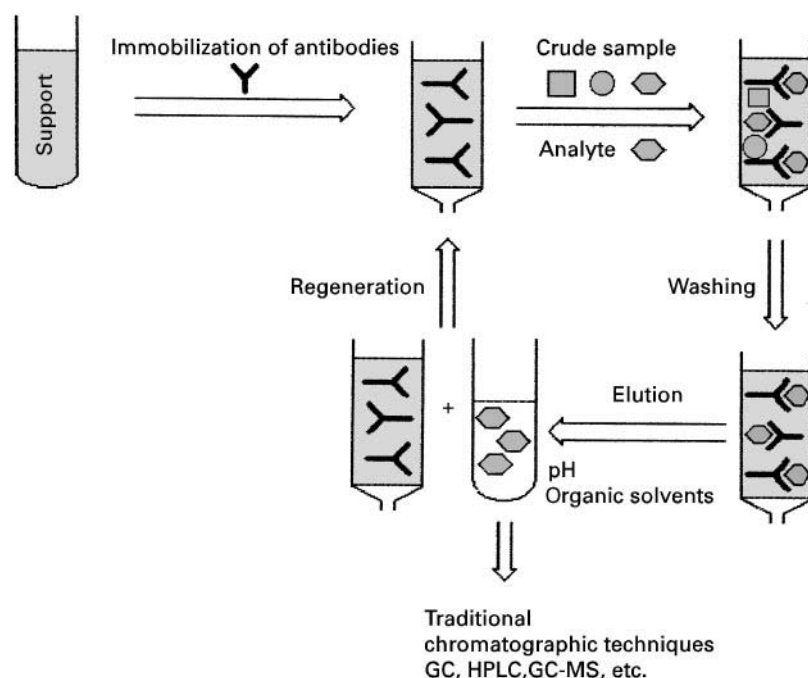

Figure 6 Schematic separation of analytes by immunoaffinity chromatography for pesticide determination in food matrices.

can overcome some of these limitations. In the LC-MS techniques, the use of an atmospheric pressure chemical ionization interface is at present the best alternative since it offers high selectivity and sensitivity for the trace determination of carbamates.

electrophoresis (HPCE), its influence in many chemical, biochemical and biomedical fields has grown constantly. New detection techniques and buffer systems have been developed to make use of the advantages offered by HPCE, such as low sample and buffer volumes, fast separations and high efficiencies. Today, sample volumes in the range of single cell liquids can be analysed. The development of highly sensitive detectors and new derivatization procedures has constantly lowered the detection limit. In the light of these advantages, the following article will focus on capillary electrophoresis.

The Electrophoretic System

Electrolyte Systems

The presence of an ionic charge is the usual prerequisite for migration in an electrophoresis system. Only some saccharides, such as aldonic acids, uronic acids, sialic acids, aminosugars or sulfated sugars of chondroitin, dermatan, keratan and heparin, possess charged functional groups in their structures. The separation of uncharged molecules requires the conversion into charged species by complex formation or derivatization.

The most commonly used systems in planar electrophoresis are those with borate buffers, but other inorganic acids can form complexes with uncharged saccharides. In HPCE, systems are based mainly on sugar-borate complexes and to a lesser extent on sugar-metal cation complexes. Boric acid in aqueous

media acts as a Lewis acid to form the tetrahedral anion B(OH)_4^- . At pH 8–10, the formation of mono- and diesters with the carbohydrates is most effective, but depends largely on the structure of that particular sugar (Figure 1).

The complexation of metal cations also depends on the structure of the carbohydrate. In addition, the ionic radius is crucial for the stability of the complex. Complexation is possible with alkaline metals, Cu^{2+} , Pb^{2+} , Zn^{2+} , Ni^{2+} and Cd^{2+} . For alkaline earth metal buffers, the separation efficiencies decrease in the following order: $\text{Ba}^{2+} > \text{Sr}^{2+} > \text{Ca}^{2+} \gg \text{Mg}^{2+}$. Another way to introduce an ionic charge is by the deprotonation of the hydroxyl functions of the sugars. For this purpose, high pH values (sodium hydroxide solutions, pH > 12) are necessary.

Carbohydrates can also be separated by micellar electrokinetic chromatography (MEKC). In this case, the separation is caused by the different distribution coefficients of the sugars between the free solution and the interior of the migrating micelles of a charged detergent (sodium dodecyl sulfate).

Detection Systems

Precolumn derivatization Most carbohydrate species do not possess strong chromophores in their structures. This condition does not allow their direct sensitive detection by UV absorption. To overcome this difficulty, carbohydrates can be tagged with suitable fluorophores or chromophores. If the tag also provides the charge necessary for electrophoresis,

uncharged carbohydrates can also be separated without the use of complexing buffer systems as well. In principle, derivatization of the hydroxyl groups should be a good approach for the tagging of carbohydrates, but the derivatization of sugars with different reactivities would lead to multiple tagging of the molecule. This would consequently cause a distribution of different products rather than a single derivative. Therefore, other functional groups of the sugar molecule must be considered. The carbonyl group in the open chain form of reducing sugars is the most widely used functional group for the attachment of the label. In amino sugars or acidic compounds, the amino group or the carboxyl group provides potential for derivatization.

Since it is required to produce only one species of derivative in precolumn derivatization, the label must not possess more than one reactive function for the attachment to the carbohydrate. Another requirement is the high molecular absorptivity (UV detection) or photoluminescence efficiency (fluorescence detection) of the tag. Although laser-induced fluorescence detection (LIF) exhibits the lowest detection limits, it is difficult to find a suitable reagent for the respective laser system. The label has to be matched to the laser system used with respect to excitation wavelength and emission intensity. Table 1 compares the detection limits of the different systems after derivatization.

The different labelling agents can be divided into three groups according to their set charge in the separation system: positive, negative or uncharged. Table 2 gives examples of some commercially available derivatization agents and the wavelengths used in different detection systems. Recently, they have found their way into standard chemical catalogues (Fluka, Sigma, Aldrich, ICN). The positively charged compounds usually contain heterocyclic nitrogen functions, e.g. 2-aminopyridine or 6-aminoquinoline. They can be protonated at lower pH values and are commonly used for separation in phosphate buffer solutions (pH 2.5–4). Depending on their pK_a values, these amino compounds can also be used as uncharged labels in high pH buffers. Chromophores with strongly acidic groups, like aminonaphthalene trisulfonic acid (ANTS), remain negatively charged over a wide pH range. Multiple sulfonic acid func-

tions introduce several negative charges to the molecules, which results in high mobility and low adsorption of the derivatives to the capillary surface. All that these compounds have in common, is that they contain a single amino function, which allows the attachment to the carbonyl function of the reducing sugar by reductive amination. In this one-pot reaction, the open chain form of the sugar reacts with the amine to a Schiff's base. To accelerate the reaction and to shift the equilibrium to the product side, the imino function is reduced by sodium cyanoborohydride to the respective secondary amine (Figure 2). An exception to this is the reaction of reducing carbohydrates with 1-phenyl-3-methyl-pyrazolone (PMP). In this case, the acidic hydrogens of PMP and the aldehyde functionality condense under slightly basic conditions.

A disadvantage of precolumn derivatization is the higher structural similarity of the compounds and the higher complexity of sample preparation. Another problem is the varying reactivity of carbohydrates, especially of monosaccharides, with the derivatizing agent. Optimized reaction conditions have to be determined for every sample mixture. The reproducibility of the sample preparation is crucial for the quantification of the compounds.

Indirect detection Indirect detection modes have been applied for the analysis of compounds whose structures lack the necessary physical properties for direct detection. The key element is the use of a background electrolyte, which provides a high, continuous signal. The analyte ion displaces the background electrolyte ion and leads to a change in the UV absorption signal. Therefore, the background electrolyte needs to have the same type of ionic charge as the analyte. The attainable detection limit is given by

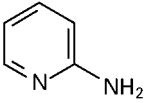

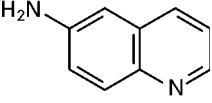

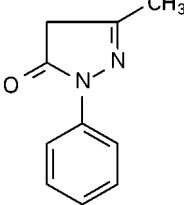

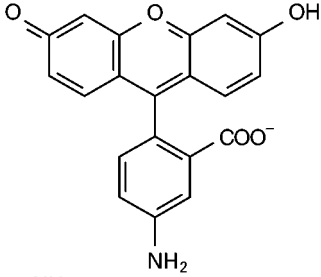

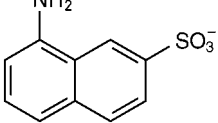

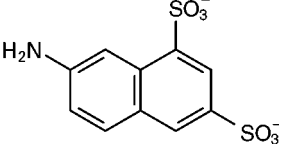

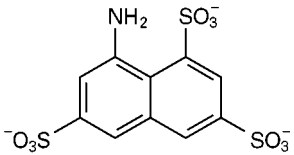

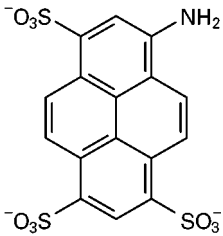

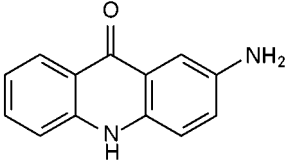

$$C_{\text{lim}} = \frac{C_M}{DR \cdot TR}$$

C_M represents the concentration of the background electrolyte, DR is the dynamic reverse and TR is the transfer ratio. DR is defined as the ability to measure a small change on top of a large signal and is equal to the signal/noise ratio of the background signal. TR is defined as the number of molecules of the background ions displaced by the charged analyte. It can be seen,

Table 1 Detection limits of monosaccharides after derivatization

Detection	Absolute amount (mol)	Concentration (mol L ⁻¹)	Weight concentration
UV derivatization	10 ⁻¹³ –10 ⁻¹¹	10 ⁻⁶ –10 ⁻⁴	ca 10 ppm
Fluorescence derivatization	10 ⁻¹⁶ –10 ⁻¹¹	10 ⁻⁹ –10 ⁻⁴	ca 10 ppb
Derivatization for LIF	10 ⁻²¹ –10 ⁻¹⁷	10 ⁻¹³ –10 ⁻⁹	ca 1 ppt

Table 2 Examples for derivatization agents and used detection wavelengths

Structure	Name	λ_{ex}	λ_{em}
	2-Aminopyridine (2-AP)	240, 320	400
	6-Aminoquinoline (6-AQ)	355	550
	1-Phenyl-3-methyl-5-pyrazolone (PMP)	245	–
	5-Aminofluorescein	257	471
	1-Aminonaphthalene-7-sulfonic acid	229	482
	7-Aminonaphthalene-1,3-disulfonic acid (ANDS)	325	520
	8-Aminonaphthalene-1,3,6-trisulfonic acid (ANTS)	223, 325	520
	8-Aminopyrene-1,3,6-trisulfonic acid (APTS)	325	520
	2-Aminoacridone (AMAC)	488	520

Figure 2 The open chain of the reducing carbohydrate reacts with the amino compound to a Schiff base, which is reduced to a secondary amine by sodium cyanoborohydride.

that C_M should be as low as possible while still generating a high DR . The TR should be close to unity.

Either indirect laser-induced fluorescence detection or UV detection can be applied to the separation of underivatized carbohydrates. Coumarin (LIF) and sorbic acid (UV), for example, have been used as background electrolytes with deprotonated carbohydrates at high pH values. In indirect detection, the concentration of the background electrolyte should be low. Thus, the use of a borate buffer (required concentrations between 0.1 and 0.25 mol L⁻¹) is excluded. Furthermore, the deprotonation of the carbohydrates at high pH values is limited by the increasing concentration of hydroxide anions, which compete with the background electrolyte ions in the displacement mechanism.

Direct detection Different modes of direct detection have been applied to HPCE separations of underivatized carbohydrates. First, low wavelength UV (below 200 nm) can be used to detect carbohydrates which have a sufficient molar absorption coefficient, especially those compounds having carboxyl or other UV-absorbing groups. Mixed oligosaccharides of heparin and heparan sulfate, chondroitin sulfate and dermatan sulfate can be detected at 232 nm. The poor absorption coefficients of many carbohydrates in the range 190 to 280 nm, limits this detection mode.

Amperometric detection Another method is pulsed amperometric detection (PAD) with gold or platinum electrodes, using a strongly alkaline buffer, which has been adapted from the HPLC-PAD systems. These systems require a specialized pulse sequence and therefore expensive instrumentation. Other systems have used ultramicroelectrodes, equipped with a 25- μm copper wire at a constant potential. These systems permit the realization of a linear range over three magnitudes and a limit of detection for mono- and disaccharides in the femtomole range. However, using PAD systems, the running buffer must not contain any electroactive species that might oxidize on the working electrode and cause a strong background signal or poison the electrode surface. Thus, amperometric detection excludes the use of borate buffers, which are essential for the separation of many neutral and native saccharides.

Refractive index detection The determination of the refractive index (RI) has shown its potential in HPLC, although it is not very sensitive and its detection limit falls below that of low wavelength UV. To overcome the problems with the low volume flow in capillary electrophoresis (CE), a sub-nanolitre laser-based refractive index detector has been developed. The detection is based on the change of interferences caused by the change of the refraction index. However, the

adaptation of RI detection of HPCE gives some problems, caused by the joule heating, which introduces changes in the temperature of the liquid and, with this, changes in the refractive index.

Capillaries with partially increased inner diameter

Theoretically, the limit of detection is reduced with the increasing inner diameter of the capillary, due to the increased lightpath through the solution. This is limited by the increasing current with constant field strength, on moving to greater diameters. High currents lead to joule heating effects and contribute to additional band broadening. Capillaries, which are widened locally at the detection window, can help to decrease the detection limit. In this case, the capillary is partially etched with hydrofluoric acid at the detection window. The reaction is controlled by temperature. The diameter widens drastically at the 'hot spot' only. The reaction rate with the capillary wall at other locations is relatively low. Using this procedure, 25- μm capillaries can be widened up to 75 or 150 μm , easily. Recently, detection cells with elongated light-path (high sensitivity cells, z cells) have become commercially available.

Applications and Separation Methods

Monosaccharides

The analysis of monosaccharides, the basic units of carbohydrates, is crucial for many areas of biochemistry, pharmacology, biotechnology and food science.

Several approaches have been made to influence the resolution of the HPCE separation of monosaccharides.

The most common buffer system is based on the complexation of the carbohydrates with an alkaline borate buffer. **Figure 3** demonstrates the separation of a mixture of several aldopentoses and aldohexoses. The sugars were tagged by reductive amination with 2-aminoanthracene. A counter-electroosmotic separation with normal polarity and fluorescence detection was performed. In this case, the intrinsic mobilities of the analytes are lower than the mobility of the electroosmotic flow (EOF). The analyte molecules are transported against their migration direction to the cathodic end of the capillary. The fastest compound is detected last. Five monosaccharides were baseline separated, while one pair (arabinose/mannose) co-migrate. The stability of the carbohydrate complex with the borate ion, which depends on the structure of the monosaccharide, has the dominating influence on the separation. Due to these differences, fucose (desoxyhexose) is separated from the unresolved pair mannose (hexose) and arabinose.

To underline the differences in the migration mechanisms, **Figure 4** shows a co-electroosmotic separation of the same mixture in an acidic medium. At a pH of 2.0, the amino function of the analyte is protonated and leads to a co-electroosmotic migration, i.e. in the same direction as the electroosmotic flow. The fastest compound is detected the first. Due to the low dissociation of the silanol groups at the capillary surface, the EOF is very low at this pH.

Figure 3 Counter-electroosmotic separation of 2-AA-labelled monosaccharides rhamnose (Rha), xylose (Xyl), glucose (Glu), arabinose (Ara), mannose (Man), fucose (Fuc), galactose (Gal) and 2-aminoanthracene (2-AA). Buffer: borate 250 mM, pH 10.5; $U = 30$ kV; capillary-fused silica, i.d. = 50 μm , $l = 88$ –100 cm; inj. 6s 100 mbar.

Figure 4 Co-electroosmotic separation of 2-AA-labelled monosaccharides rhamnose (Rha), xylose (Xyl), glucose (Glu), arabinose (Ara), mannose (Man), fucose (Fuc), galactose (Gal), maltotriose as standard (M3ose) and 2-aminoanthracene (2-AA). Buffer: phosphate 100 mM, 20% (v/v) iPropOH, pH 2.0; capillary fused silica, $l = 49\text{--}60$ cm, i.d. = $50\text{ }\mu\text{m}$; $U = \text{ramp } 2.5\text{ kV min}^{-1}$ from 5 to 30 kV; inj. 6s 100 mbar.

To enhance resolution, an organic modifier (isopropanol) was added. The co-electroosmotic separation leads to a different electropherogram. Here, other parameters, such as the hydrodynamic radius of the analytes, have the dominating influence on the migration mechanism. The differences in mobility of mannose, fucose and arabinose are too small to lead to a separation, while the resolution of the epimers glucose and mannose is increased compared to the borate buffer system.

It is also possible to separate a monosaccharide mixture by micellar electrokinetic chromatography (MEKC). In this system, the dominating mechanism is the dynamic distribution of the uncharged analytes between free solution and the migrating micelles of the detergent (often SDS). Here, other properties of the analytes, such as differences in their hydrophobicity, effect the separation.

Figure 5 shows the separation of a monosaccharide mixture in a trisborate/SDS buffer. Unlike the results of the previous separation systems, the peaks of mannose and arabinose show a sufficient resolution.

Table 3 gives some examples of the buffer systems and tags used so far to analyse monosaccharide mixtures. The use of borate buffers dominates. Other systems have also been used, but have not yet found their way into standard applications.

Linear Oligo- and Polysaccharides

Oligo- and polysaccharides can be classified either as homo- or heteropolymers, depending on whether

they consist of one type or more than one type of monosaccharide unit that alternate in the repetitive sequence. High molecular weight polysaccharides are usually analysed through their degradation products (chemical or enzymatic cleavage). The systems described for the separation of monosaccharides can be easily applied to the separation of oligosaccharides. With few exceptions, the mobilities decrease with increasing molecular weight of the analytes. The use of divalent metal ions for complexation is not favourable for analysing carbohydrates, as it leads to insufficient separation efficiency.

The composition of oligosaccharide mixtures should be considered when selecting the separation system. The use of a borate buffer focuses on the structural differences of the oligosaccharides and should be used for separation of heterogeneous oligosaccharides with the same degree of polymerization. For homologous oligosaccharides, the use of permanently charged labels in a co-electroosmotic system is favourable. Here, the charge-to-mass ratio is the dominant parameter responsible for the migration differences. The influence of the electroosmotic flow should be reduced to a minimum to ensure good resolution of the compounds with higher molecular mass.

Figure 6 shows the counter-electroosmotic separation of 2-AA labelled maltooligosaccharides in the borate buffer system. As the molecular weight increases, the differences in migration time decrease very fast. This can be explained by a lower degree of

Figure 5 MEKC separation of 2-AA-labelled monosaccharides. 1, rhamnose; 2, cellobiose; 3, xylose; 4, ribose; 5, glucose; 6, mannose; 7, arabinose; 8, galactose; 2-AA, 2-aminoanthracene. Buffer: trisborate 100 mM/urea 4 M/SDS 100 mM, pH 8.3; capillary-fused silica, $l = 48\text{--}60$ cm, i.d. = 25 μm ; $U = 30$ kV.

structural change, going step by step to higher degrees of polymerization. Also, the ratio of $\mu_{\text{analyte}}/\mu_{\text{EOF}}$ decreases with increasing degree of polymerization. With a higher degree of polymerization, the mobility

differences decrease drastically and lead to insufficient resolution.

For higher degrees of polymerization (> 7), the use of charged labels at low EOF is to be preferred.

Table 3 Examples of the separation mode, buffer systems and detection methods for different carbohydrates

Analytes	Detection	Separation mode	Derivatization	Buffers
Monosaccharides	Direct UV	CZE	2-AP	200 mM borate, pH 10.5
Monosaccharides	Direct Fluorescence	CZE	2-AA	200 mM borate, pH 10.5
Monosaccharides	Indirect UV	CZE	–	6 mM sorbate, pH 12.1
Monosaccharides	Indirect LIF	CZE	–	50 μM fluoresceine, pH 12.2
Monosaccharides	Direct LIF	CZE	APTS	25 mM borate, pH 10.0
Monosaccharides	Amperometric detection	CZE	–	100 mM NaOH, pH 13
Monosaccharides	RI detection	CZE	–	100 mM borate, pH 9.0
Maltooligosaccharides $\text{DP}_{\text{max}} < 25$	Direct UV	CZE	2-AP	100 mM phosphate, pH 2.5
Maltooligosaccharides	Direct LIF	CZE	ANTS	50 mM phosphate, pH 2.5
Branched xyloglucans	Direct UV	CZE	2-AP	100 mM phosphate, 50 mM tetrabutylammonium bromide, pH 4.75
Dextrans $\text{DP}_{\text{max}} < 25$	Direct fluorescence	CZE	2-AA	100 mM phosphate, pH 2.0
Low molecular weight heparin	Direct UV	CZE	–	10 mM borate, 50 mM sodium dodecyl sulfate
Polygalacturonic acid $\text{DP}_{\text{max}} < 70$	Direct LIF	CGE	ANTS	100 mM Tris, 25 mM borate, pH 8.5
Hyaluronic acid $\text{DP}_{\text{max}} < 400$	Direct LIF	CGE	APTS	Polyacrylamide gel, 18% T, 3% C
Glycoforms of ribonuclease A	Direct UV	CZE	–	25 mM citric acid, 12.5 mM tris, 0.03% aminodextran (mol. wt 10 000)
				20 mM phosphate, 50 mM sodium dodecyl sulfate, 5 mM borate, pH 7.2

DP_{max} , maximum degree of polymerization (baseline separation); CZE, capillary zone electrophoresis; CGE, capillary gel electrophoresis.

Figure 6 Counter-electroosmotic separation of the starch hydrolysate Dextrin 10 (numbers indicate the degree of polymerization). Buffer: borate 300 mM, pH 10.5; capillary fused silica, $l = 108\text{--}120$ cm, i.d. = $50\text{ }\mu\text{m}$; field = 30 kV; inj. 6s 100 mbar.

It can be seen in **Figure 7** that protonation of the amino function of the 2-aminoanthracene-labelled aminoglycans leads to a higher resolution of the oligosaccharide peaks. With a higher number of monosaccharide units, the mobility differences decrease less than those in the borate system. Increasing charge of the label can increase the mobility of the molecules. This has proved to be the case with naphthalene di- and trisulfonic acid derivatives especially. By derivatizing with aminonaphthalene trisulfonic acid, it is possible to separate more than 30 malto-oligomers within 10 min.

To improve the resolution of homologue oligosaccharides with a higher degree of polymerization, two different approaches have been attempted. First, the use of coated capillaries (polyether, polyvinyl alcohol) showing very low or virtually no electroosmotic flow can lead to an increase in resolution. The disadvantages of these systems are the limited pH range in which they can be used and the high cost of the capillary material.

A similar approach to that for the separation of oligonucleotides involves using gel-filled capillaries. Gel-filled capillaries can have a sieving effect on the

Figure 7 Co-electroosmotic separation of the starch hydrolysate Dextrin 10 (numbers indicate the degree of polymerization). Buffer: phosphate 100 mM, pH 2.0; capillary-fused silica, $l = 49\text{--}60$ cm, i.d. = $50\text{ }\mu\text{m}$; $U = 25$ kV; inj. 5s 100 mbar.

analytes. This size discrimination can be used to increase the differences in mobility. Unfortunately, the use of gel-filled capillaries is accompanied by many difficulties such as poor gel-to-gel reproducibility, bubble formation, quenching effects by the matrix, and the collapse of the gel matrix buffer. Another problem is the relatively low mobility of the formerly uncharged molecules, which are tagged by a charged label. The use of gel-filled matrices can increase the migration time to an unacceptable extent.

For structures consisting of charged monosaccharide species, such as polyuronic acids, the use of a mixture of aminodextran and linear polyacrylamide (LPAA) as buffer additive is successful. In this case, the retention mechanism cannot be due to the sieving effect of the matrix only. The system is, rather, based on size-dependent electrostatic interactions between the protonated amino functions of the aminodextran and the dissociated carboxylic groups of the uronic acids.

Table 3 gives some examples of the systems used so far.

Branched Oligosaccharides

Branched oligosaccharides can be produced by enzymatic digestion of branched heteropolysaccharides, for example xyloglucan polysaccharides. In combination with a charged label, some information about the branching of the compounds can be achieved. If only the label is charged, the compounds migrate in order of increasing size, as shown before. With similar molecular weight, the less branched oligosaccharides migrate faster than the more branched ones. For branched xyloglucan oligosaccharides, a mobility index system has been introduced to describe the migration behaviour of the branched compounds with respect to their linear homologues. The equation below shows how the mobility index (MI) can be calculated:

$$MI = 100n + 100 \left(\frac{\log \mu_s - \log \mu_{n+1}}{\log \mu_n - \log \mu_{n+1}} \right)$$

μ_s is the electrophoretic mobility of the branched analyte, and μ_n and μ_{n+1} are the electrophoretic mobilities of the two homologues with n and $n+1$ repetitive units, which migrated before and after the branched fragment. This index system can only be applied if the following requirements are fulfilled. First, the system must consist of homopolymers or heteropolymers with a strictly repeating sequence. Second, the logarithmic mobilities of the homologues must show a logarithmic dependence on the degree of polymerization, which is not always the case.

Glycoconjugates

Glycoproteins Glycoproteins function as enzymes, transport proteins, receptors, hormones and structural proteins. The carbohydrate content of glycoproteins can vary from less than 1% to more than 60% by weight. Protein glycosylation can occur at two or more positions in the amino acid sequence. The glycans at a single position may be heterogeneous or may be missing from some molecules. This leads to populations of glycosylated species of a single protein (glycoforms). The relative proportions of glycoforms are found to be reproducible, depending on the glycosylation conditions (environment of the reaction, physical state and type of organism), the manufacturing process and the isolation procedures.

On the one hand, glycoform separation and mapping has to cope with the problems introduced by the protein moiety, such as interactions of the protein with the capillary wall in low pH electrolyte systems. In this case, a hydrophilic coating of the capillary surface can avoid adsorption phenomena. On the other hand, the UV absorption coefficients at 200 nm are sufficient for the detection of the compounds without precolumn derivatization. Common buffer systems are phosphate, TRIS/boric acid or borate buffers, depending on the separation mode and the pH range.

Glucosaminoglycans Glucosaminoglycans (mucopolysaccharides) are unbranched polysaccharides of alternating uronic acid and hexosamine residues, for example, heparin, chondroitin sulfate, dermatan sulfate or hyaluronic acid. After exhaustive treatment with polysaccharide lyases, disaccharides can be obtained bearing unsaturated uronic acids. These compounds can be detected directly at 232 nm. To enhance sensitivity, they can also be labelled. Since the mucopolysaccharides are already charged over a wide pH range, it is not necessary to introduce a charge by a tag or complexation. The use of SDS micelles can increase the resolution.

Glycolipids Some lipids contain oligosaccharide moieties as an integral part of their structure. Since these contain a hydrophilic head and a hydrophobic tail, they form micellar systems. Temperature, concentration of the analyte and ionic strength of the electrolyte system are crucial for the size and mobility of the micelles. Thus, the separation of some glycolipids as monomeric species is impeded. The investigations made so far have been based on phosphate buffer systems and low wavelength UV detection.

Further Directions

Capillary electrophoresis has proven potential for carbohydrate analysis. High efficiencies and short analysis times are its advantages compared with other analytical separation methods. A variety of different separation modes can be applied to separate complex carbohydrate mixtures. It has been shown that, depending on the properties of the sample, different separation methodologies can be applied and optimized.

The electrophoretic analysis of carbohydrates is still under development. In particular the analysis of biochemical compounds, such as glycoconjugates, is still a challenge and can give new information about cell mechanisms, structure of antibodies, etc. This article has focused on the basic aspects of capillary electrophoresis of carbohydrates. The carbohydrates described were confined to simple model compounds. For more specific information, the Further Reading list should be consulted.

Overview of Derivatization of Sugars for GC, GC-MS or GC-MS-MS Analysis

Table 1 overviews many of the important events in chromatographic and mass spectrometric analysis of sugar monomers. These will be discussed at appropriate points in this review. It was not until the years 1961–1963 that gas chromatography (GC) was applied to the quantitative analysis of mixtures of neutral and amino sugar monomers, even though individual sugars had been derivatized earlier. Carbohydrate analysis by GC lagged behind the analysis of many other compounds because of the difficulty in producing volatile derivatives. Two schools of

thought developed, relating to whether the anomeric centre should be retained or destroyed in derivatization. Both persist to this day. Sugars exist in equilibrium between ring and straight chain forms. If the anomeric centre is not eliminated, derivatization fixes the sugars in the anomeric ring forms. Thus, two to four peaks will be produced from each L or D sugar (two from furanose and two from pyranose anomers). Interpretation of chromatograms becomes complicated and quantitation difficult. Acidic sugars (i.e. generally with carboxyl groups) require additional derivatization steps. The carboxyl moiety may be converted to a lactone, ester or reduced to an alditol.

The Alditol Acetate Procedure

The alditol acetate procedure was the first developed in which the anomeric centre is eliminated. The anomeric centre is converted by borohydride reduction (although later borodeuteride was introduced)

Table 1 Important advances in analysis of carbohydrates

to an alcohol prior to acetylation (to produce a volatile derivative). Unfortunately, borate derived from the added borohydride, or borodeuteride, inhibits the subsequent acylation step. The classical procedure employs a multi-step evaporation with methanol–acetic acid to remove borate as tetramethyl borate gas in between the reduction and acetylation steps (Figure 1).

In the 1960s, sodium acetate and pyridine were introduced as catalysts for acetylation, pyridine being more efficient than sodium acetate. However, in both cases borate must be removed prior to acetylation. Subsequently, several catalysts (including methylimidazole) were described that allowed acetylation without removal of borate or moisture. Unfortunately, many catalysts (including both pyridine and methylimidazole) often generate side-reaction products (from reaction with acetic anhydride) that produce chromatograms contaminated with extraneous peaks. Furthermore, in the presence of moisture

and/or borate, acetylation can be somewhat unpredictable. When using sodium acetate as a catalyst following removal of borate and moisture, these problems do not occur but unfortunately, the process to remove borate and moisture is tedious to perform. An automated evaporator has been developed to perform the multiple cycles of methanol–acetic acid addition/evaporation for borate removal in the alditol acetate procedure. More recently, an automated derivatization instrument has been developed to automate the entire alditol acetate procedure.

The Trimethylsilyl Procedure

Also in the early 1960s, other workers described a simple one-step trimethylsilyl derivatization of hydroxyl groups. This remains one of the most common procedures used for GC analysis. Derivatization is readily achieved. However, complex chromatograms are produced due to anomer formation noted above. Also, analysis must be prompt since the derivatives

Figure 1 An example of an alditol acetate derivatization reaction employing sodium borodeuteride in the reduction step. Differences in the mass spectra of ribose and ribitol illustrate the distinctness of mass spectra of alditols and aldoses.

decompose in the presence of moisture, complicating clean-up of complex samples.

The Aldonitrile Acetate and O-Methyloxime Acetate Procedures

Procedures developed in the 1970s involving destruction of the anomeric centre were particularly concerned with proceeding directly to the final acylation step. Such procedures generally employed acetylation as the final acylation step due to the stability of acetylated sugar derivatives. Such methods included the aldonitrile acetate and the O-methyloxime acetate procedures. To generate the former, the aldehyde is reacted with hydroxylamine to produce an oxime which is converted to a nitrile on acetylation. O-methyloxime acetates, on the other hand, are prepared by destruction of the anomeric centre by reaction with O-methyl-hydroxylamine, also followed by acetylation. Unfortunately, O-methyloxime acetates display a new isomeric centre and two products, syn- and anti, are generated for each sugar.

An advantage of both aldonitrile and O-methyloxime acetate methods is that aldoses produce distinct peaks from alditols. However, substitution of borodeuteride for borohydride reduction (in alditol acetate formation) labels the aldose group, whilst alditols remain unlabelled. Thus, aldoses and alditols can be distinguished by gas chromatography–mass spectrometry (GC-MS) analysis. Alternatively, alditols do not contain an anomeric centre and can be acetylated without prior derivatization steps (e.g. reduction) and are simply analysed. This also allows discrimination of alditols from aldoses. For further details see the section on GC-MS analysis of alditol acetates, below.

The Trifluoroacetyl Procedure

Trifluoroacetyls, like trimethylsilyl derivatives, are also formed by a simple one-step derivatization procedure. However, as with trimethylsilyl derivatives, multiple peaks are generated for each sugar and are unstable on exposure to moisture. Therefore, samples must be analysed soon after derivatization. As noted above, acetate derivatives are generally stable indefinitely.

Chiral Derivatives

Methods developed have followed two approaches: after conventional derivatization (e.g. permethylation) enantiomers (L and D isomers) can be separated on chiral (e.g. cyclodextrin) GC columns; alternatively, glycosidation with chiral reagents (e.g. an optically active alcohol such as butanol) produces diastereoisomers that can be resolved on conventional nonchiral capillary columns.

Choice of Derivatives for Instrumental Detection

Most reports in the 1960s and 1970s employed the flame ionization detector (FID). While the FID is useful as a GC detector, it lacks specificity. The use of the mass spectrometer (MS) or tandem mass spectrometer (MS-MS) as a GC detector dramatically expands the capability of the analysis. GC-MS, using electron impact ionization (EI) or chemical ionization (CI) followed by positive ion detection, employs the same derivatives as in FID but provides specificity that the FID lacks.

There have been a few reports using the electron-capture detector (ECD) offering the possibility of increased sensitivity if a halogenated (electron-capturing) derivative such as trifluoroacetyl, pentafluoropropyl or heptafluorobutyl is employed. Unfortunately, such derivatives are unstable in the presence of moisture. Furthermore, compounds other than sugars may be converted to halogenated derivatives, resulting in increased background. Thus, it is unclear whether the increased sensitivity can be utilized. An unusual derivative not widely used is the O-pentafluorobenzyl oxime acetate derivative. For this derivative, pentafluorobenzyl oxime replaces the aldehyde as the electron-capturing group prior to acetylation. Unlike other halogenated derivatives, the O-pentafluorobenzyl oxime acetate is stable to moisture. Alternatively, such derivatives might be appropriate for use with MS in the negative ion mode. Like ECD, negative ion chemical ionization (NI-CI) GC-MS also necessitates an electron-capturing derivative. Use of GC-MS-MS might take further advantage of the increased sensitivity of NI-CI since background is essentially eliminated.

The first benchtop GC-MS instruments were introduced in the late 1970s and had only EI capability. Later instruments could perform both EI and CI with both positive and negative ion detection capabilities. In the past 3–4 years, comparably priced benchtop GC-MS-MS instruments, also with EI-CI and positive/negative ionization capability, have been introduced. Most GC-MS and GC-MS-MS analyses of sugars are still performed with EI in positive ion detection mode. These instruments are simple to operate and maintain and are run by Windows-based PCs.

Preparation of Alditol Acetate Derivatives of Sugars Present in Complex Matrices

Steps in the analysis of complex sugar mixtures include release of the sugar by hydrolysis, addition of internal standard, derivatization and instrumental

analysis. Examples of analyses performed with the alditol acetate procedure will be used here to illustrate these steps.

Hydrolysis

There have been numerous articles on the selection of hydrolysis conditions. Parameters requiring consideration include temperature, duration and the type and strength of acid (primarily hydrochloric, sulfuric and trifluoroacetic acids). Optimization is highly dependent on the sugar(s) of interest to be released from a particular polymeric matrix. If the hydrolysis conditions are too gentle, there is an inadequate release of the sugar monomers. Conversely, if the conditions are too harsh, then destruction of certain sugars occurs. Neutral sugars are often easier to release and destroy than aminosugars. Invariably, a compromise must be made in the analysis of a mixture of neutral and aminosugars in a complex matrix. It must also be recognized that it is not the absolute amount of polymeric sugar present in the matrix that is being determined, but the amount released as monomers under the selected hydrolysis conditions.

Following hydrolysis and prior to derivatization, the acid must be removed. Trifluoroacetic and hydrochloric acids are generally removed by evaporation. Under these conditions further destruction of sugars is possible. Sulfuric acid can be removed by neutralization with a solution of barium hydroxide or a suspension of barium carbonate. Unfortunately, on neutralization with a barium hydroxide solution, it is difficult to remove the sugar from the precipitate of barium sulfate. The use of barium carbonate is not practical because a coat of barium sulfate forms, protecting a large portion of the particulate barium carbonate from reacting. Thus, large quantities of barium carbonate are needed for neutralization. A simple alternative involves neutralization with a solution of an organic base (*N,N*-diethylmethylamine) in chloroform. Sugars remain in the aqueous phase and sulfate is removed in the organic phase.

Choice of Internal Standard

There is a great deal of variability of sugar monomers that can be present in complex biological matrices. Quantitation of each sugar present in a profile is desirable, but it is not practical to select one internal standard for each sugar. Generally, internal standards are selected for groups of sugars based on structural similarities. On SP-2330 columns, neutral sugars elute much earlier than aminosugars. Relative standard deviations (RSD) for multiple samples on GC analysis for late-eluting aminosugars are high if an early eluting neutral sugar (e.g. arabinose) is used as the internal standard. Selection of a late-eluting

aminosugar (e.g. methylglucamine) as an internal standard for aminosugars dramatically increases precision. However, on less polar columns, such as the DB-5ms, certain high molecular weight neutral sugars (e.g. heptoses) tend to elute in the same region as aminosugars (e.g. aminohexoses). In the analysis of heptoses, when using arabinose as the internal standard (by comparing relative peak areas), the RSD for D-glycero-D-mannoheptose and L-glycero-D-mannoheptose was found to be 25.3% and 30.7%, respectively. Using methylglucamine, RSD was lowered to 11.0 and 7.2%. This suggests that, when selecting an internal standard, the relative retention time of the eluting sugars, rather than similarity in structure, may be more critical. Heptoses are highly characteristic of Gram-negative bacteria.

The aldoses L-glycero-D-mannoheptose and D-glyceroheptose are not available commercially. On reduction they are converted into their respective heptitols. However, the ketose heptulose, which is available commercially, on reduction generates both L-glycero-D-mannoheptitol and D-glycero-D-mannoheptitol. Hydrolysates of *Escherichia coli* contain L-glycero-D-mannoheptose but not D-glycero-D-mannoheptose. Thus, by comparing chromatograms of standards containing heptulose and hydrolysates of *E. coli* (as alditol acetates) it is possible to identify the two heptose peaks. Figure 2 shows a typical separation of a mixture of neutral and amino sugar standards (including both heptose peaks) on a DB-5ms fused silica capillary column and a hydrolysate of *E. coli* (containing L-glycero-D-mannoheptose but not D-glycero-D-mannoheptose).

The Automated Derivatization Instrument for Preparation of Alditol Acetates

The manually performed alditol acetate derivatization procedure described elsewhere has been used for many years. This multi-step procedure can now be performed sequentially by a computer-controlled instrument. The procedure, which previously took 2½ working days, is performed in an automated fashion, requiring a total of 90 min manual work. The samples are processed in four stages:

1. evacuation/hydrolysis (3 h 15 min, automated);
2. prederivatization clean-up (1 h, manual);
3. alditol acetate derivatization (23 h, automated);
4. post-derivatization clean-up (30 min, manual).

The core of the machine, where chemical manipulations and reactions are performed, consists of a custom-built manifold with 21 glass chambers, to each of which a test tube is attached. The manifold is seated in a movable heating block. A series of electrically driven solenoid valves are attached in-line with

Figure 2 Selected ion monitoring (SIM) GC-MS chromatograms of alditol acetates (A) sugar standards and (B) hydrolysate of *Escherichia coli*. The following m/z were monitored: 160 (deoxyribose); 171 (rhamnose and fucose); 145 (ribose, arabinose and xylose); 199 (inositol, 199); 290 (mannose, glucose and galactose); 318 (glucosamine, galactosamine, mannosamine); 362 (D,D-heptose and L,D-heptose); 168 (muramic acid); 327 (methylglucamine).

the manifold. A set of solvent valves control the input of solvent and/or nitrogen gas to each sample chamber. A set of gas valves controls output to atmosphere or vacuum. Additionally, closure of all valves allows the samples to be sealed in a closed chamber.

Computer control of the individual stages of the derivatization process is a major feature of the system. Ten mg of each sample, in 1 mL of 2 mol L⁻¹ sulfuric acid, is placed in each of the custom test tubes. The samples are attached to the manifold and the program started. Oxygen is evacuated by repeated alternate exposure of nitrogen and vacuum. After evacuation, the program sets the heating block to 100°C for hydrolysis. Heating continues for 3 h under nitrogen.

Following hydrolysis, internal standards are added, the samples are removed from the instrument, neutralized with 2 mL 50% N,N-dioctylmethylamine (Fluka, Buchs, Switzerland) in chloroform, and then centrifuged. The aqueous phase containing the sugar monomers is removed and passed through C₁₈ columns (J&W, Folsom, CA) into 21 new sample tubes via the evacuated 21-chamber manifold described above. Aqueous sodium borodeuteride 200 µL (25 mg mL⁻¹) is then added to each sample.

The derivatization procedure is entirely under computer control. After a 2 h delay, in which sample reduction occurs at room temperature, methanol–acetic acid (200:1 v/v) is added by activation of a solenoid valve connected to a reagent reservoir. The

program then sets the heating block to 60°C, and evaporation under N₂ occurs for 30 min. This step (solvent addition and evaporation) is automatically repeated several times to remove borodeuteride as tetramethyl borate gas. After the last addition, the system is evacuated by activation of the attached vacuum pump, and the samples are dried for 4 h at room temperature. Acetic anhydride is then added to the samples from another reservoir, and the samples acetylated for 13 h at 100°C. Finally, the samples are evaporated to dryness under N₂, and chloroform is added from a third reservoir.

The final post-derivatization clean-up (taking 30 min) is performed manually but also uses the 21-sample manifold, alleviating the necessity for additional equipment. Samples are passed through a pair of connected Chem-Elut columns (Varian, Walnut Creek, CA), the first pre-treated with 2 mol L⁻¹ acetic acid and the second with 14.8 mol L⁻¹ ammonium hydroxide. The chloroform eluent is evaporated under N₂, and samples reconstituted for analysis.

Instrumental Analysis of Alditol Acetate Derivatives

Columns of GC Analysis

There was a great deal of work in the early days in the selection of packed columns for separation of a complex mixture of neutral and amino sugars by GC. This work was readily extrapolated to the vastly improved fused silica columns introduced later. As an example, excellent capillary GC separation of neutral and aminosugar mixtures is obtained on relatively polar SP-2330 columns. However, aminosugars require high final temperatures and/or extended run times for elution and this column tends to display poor temperature stability under such conditions. Furthermore, irreversible adsorption of aminosugars is a significant problem, causing poor sensitivity of the aminosugars relative to neutral sugars. More recently, nonpolar DB-5ms columns have been used which have not exhibited these problems. In complex mixtures, sugars are observed as sharp peaks with almost baseline resolution. It would be highly desirable if a commercial column were developed that displayed the stability of the DB-5ms column but had the resolving capacity of the SP-2330 column.

GC-MS Analysis of Alditol Acetates (Total Ion Spectra and SIM)

Using total ion GC-MS, carbohydrate monomers can readily be identified by their characteristic ion spectra. Once the sugar has been identified, a particular ion or set of ions characteristic of that monomer

can be chosen for selected ion monitoring (SIM). Once retention time has been established, SIM chromatograms allow for clean, easily quantifiable peaks for each monomer. Figures 3 and 4 compare total ion and SIM GC-MS analysis of two bacterial hydrolysates (*Bacillus subtilis* strains 168 and W23). In the total ion chromatograms there are a number of tiny background peaks (e.g. the glucose and methylglucamine peaks both have shoulders). The extraneous peaks are eliminated in the SIM chromatograms. Furthermore, sensitivity is dramatically increased in SIM analysis. This is illustrated in that galactosamine is readily detected in the SIM – but not the total ion chromatogram – for strain 168. In such analyses, generally µg amounts of sugars are present but, in our experience, SIM GC-MS can be used to detect as little as 100–250 ng in complex samples (10–20 mg of starting sample). However, background peaks become increasingly more of a problem as the concentration of sugar is decreased.

As noted above, a native sugar forms 2–4 anomers upon acylation, thus creating multiple peaks from a single sugar and complicating chromatograms. The anomeric centre is usually first destroyed. If hydroxylamine and O-methylhydroxylamine are used in the acylation of carbohydrate monomers, aldononitrile acetates and O-methyloxime acetates, respectively, generate distinct chromatographic peaks for aldoses and alditols. This is not the case for alditol acetates.

Sugars are generally reduced using sodium borohydride or borodeuteride prior to acylation to eliminate anomer formation. For example, during reduction of aldoses the C₁ aldehyde is converted to an alcohol (i.e. aldose to an alditol), whereas alditols remain chemically unchanged. Using sodium borohydride, in the formation of alditol acetates, aldoses and alditols cannot be differentiated. However, when using sodium borodeuteride, two deuteriums are added to the aldehyde moiety, one of which remains after acylation. Thus, there is a one mass unit shift in ions containing C₁. Fragments lacking C₁ generate ions of the same *m/z* for deuterated and nondeuterated samples.

As an example, *B. subtilis* W23 is readily discriminated from *B. subtilis* 168 by the presence of a ribitol containing polysaccharide (teichoic acid). Total ion and SIM chromatograms of carbohydrates derived from these two bacterial strains are shown in Figures 3 and 4 respectively. During hydrolysis, ribitol is released from the teichoic acid. Unfortunately, RNA releases ribose upon hydrolysis which is converted to ribitol upon reduction, thus hindering the detection of ribitol originating from teichoic acid. However, ribitol from teichoic acid is also partially

Figure 3 Total ion GC-MS chromatograms of alditol acetates of hydrolysates of *Bacillus subtilis* (A) strain W23 and (B) strain 168. Ribose is present at 1.13% of the dry weight of the sample of W23 analysed (total 10 mg), i.e. 113 μg .

converted to anhydrosorbitol during hydrolysis. Strain W23 can therefore be readily distinguished from strain 168 by the presence of anhydrosorbitol. The mass spectrum of anhydrosorbitol and its structure are shown in Figure 5. The molecular weight of anhydrosorbitol is 260; m/z 187 (M-73, breakage between C_4 and C_5 , which leaves the ring intact), m/z 127 (loss of acetic acid, 60) and m/z 85 (loss of ketene, 42).

On examination of SIM chromatograms, the ribitol/ribose peak cannot be used to distinguish the two organisms. However, this can be accomplished by full scan (GC-MS) analysis. As noted above, on borodeuteride reduction, aldoses (e.g. ribose) gain two deuteriums, one of which remains after acylation, while alditols (e.g. ribitol) remain unchanged. For aldoses, pairs of peaks are generated, from the

C_1 end labelled with deuterium and the other, unlabelled end. For alditols, C_1 is not labelled, resulting in single peaks. Thus, the mass spectrum of ribose contains pairs of ions of nearly equal abundance (i.e. m/z 115/116, 145/146, 187/188 and 217/218) generated from the two ends of the molecule, while ribitol would be dominated by single ions (i.e. m/z 115, 145, 187 and 217). Therefore, for strain W23 where ribitol, in addition to ribose, is present, the mass spectrum contains a greater abundance of the lower mass ion of each pair than for strain 168 (where ribose alone is present). Figure 6 clearly demonstrates that standard ribose has a mass spectrum indistinguishable from the ribose peak derived from the hydrolysate of strain 168. However, the peak for strain W23, containing a mixture of ribose and ribitol, is readily distinguished by the dominance of

Figure 4 Selected ion monitoring GC-MS chromatograms of alditol acetates of hydrolysates of *Bacillus subtilis* (A) strain W23 and (B) strain 168. Same ions as Figure 2 plus 187 (anhydrosorbitol).

115 over 116, 145 over 146, 187 over 188 and 217 over 218.

The base peak in EI mass spectra of alditol acetates is generally dominated by the acetylinium ion (m/z 43). Many primary fragments are produced by cleavage between sequential carbon atoms. Secondary fragmentation results from losses of acetic acid (m/z 60), acetoxyl groups (m/z 59) and ketene (m/z 42). Generally, mass spectra of aminosugars are relatively simple since cleavage preferentially occurs between the carbon with attached acetamido group and adjacent acetylated carbons.

Mass spectra of stereoisomers of alditol acetates contain ions of the same m/z . On casual observation the mass spectra appear similar. However, certain isomers display differences in relative ion abundances

which can be quite striking. Aminodideoxyhexoses, quinovosamine and fucosamine (found in legionellae), have been noted to display distinct mass spectra. Differences in mass spectra among isomers are accentuated by the use of borodeuteride. Aldoses are asymmetric since there is an aldehyde on C_1 . Asymmetry is retained after borodeuteride but not borohydride reduction since C_1 is labelled. It has been proven that all eight hexoses can be differentiated by a combination of distinct mass spectra and/or retention times.

Muramic acid, 3-O-lactyl glucosamine, is an unusual sugar which additionally contains a carboxyl group in ether linkage. A lactam (a cyclic amide) is formed by internal dehydration between its carboxyl and amino groups on derivatization. In contrast to

Figure 5 Mass spectrum of alditol acetate of anhydrosorbitol derived from hydrolysate of *Bacillus subtilis* W23.

acetylation of other aminosugars, which produce amides, muramicitol pentaacetate (acetylated muramic acid) has an imido group in which two acyl groups, lactyl and acetyl respectively, are linked to the nitrogen atom. Formation of the imido moiety requires harsh conditions (higher temperatures and longer heating times).

Naturally occurring O-methylated sugars exist in bacteria and in eukaryotes. The fragmentation pattern of methylated sugars is distinctive. Fragmentation between the O-methylated carbon and the adjacent acetylated carbon atoms dominates the spectra. Additional secondary ions can be produced by loss of methanol (m/z 32) and formaldehyde (m/z 30).

GC-MS-MS Analysis of Alditol Acetates (Multiple Reaction Monitoring and Product Ion Spectra)

High resolution chromatographic separations coupled with selective clean-up steps are important in improving the specificity of the detection of chemical markers (e.g. muramic acid as a marker for bacterial infection) in complex matrices. However, chromatographic separation is not sufficient to eliminate extraneous peaks when nonselective detectors are employed. The use of the mass spectrometer as a selective GC detector (i.e. GC-MS analysis in SIM), helps greatly in diminishing background noise by focusing only on ions that are present in the compound of interest. However, even when using SIM, it is not uncommon to find extraneous background peaks. The tandem mass spectrometer, as a GC detector,

provides even greater specificity in detecting trace amounts of chemical markers in complex matrices. Tandem mass spectrometry has the added advantage of generating a total ion spectrum from a selected precursor ion (product ion spectrum). The resulting product ion spectrum can be used for a definitive identification of the compound of interest at trace levels.

Multiple reaction monitoring (MRM) and generation of product ion spectra both involve three discrete mass analysis steps. The first stage involves selection of a precursor ion. This instrumental clean-up removes other ions. The precursor ion is then fragmented by collision-induced dissociation (CID) using an inert gas. In the third stage, all precursor ions can be collected (product ion spectrum) or a single product ion is selected for monitoring (MRM). Both SIM GC-MS and MRM GC-MS-MS analysis allow excellent quantitation of such chemical markers, but the latter provides much greater confidence in trace analysis.

Two types of GC-MS-MS instruments are primarily used in such analysis: ion traps and triple quadrupoles. In triple quadrupole instruments, the three stages of analysis are performed using three distinct quadrupole mass analysers. There is some decrease in sensitivity due to loss of ions in transmission through the three quadrupoles. In ion trap tandem mass spectrometers, the three stages occur in the same mass analyser. This dramatically simplifies the instrument and its cost. Furthermore, sensitivity of MS-MS

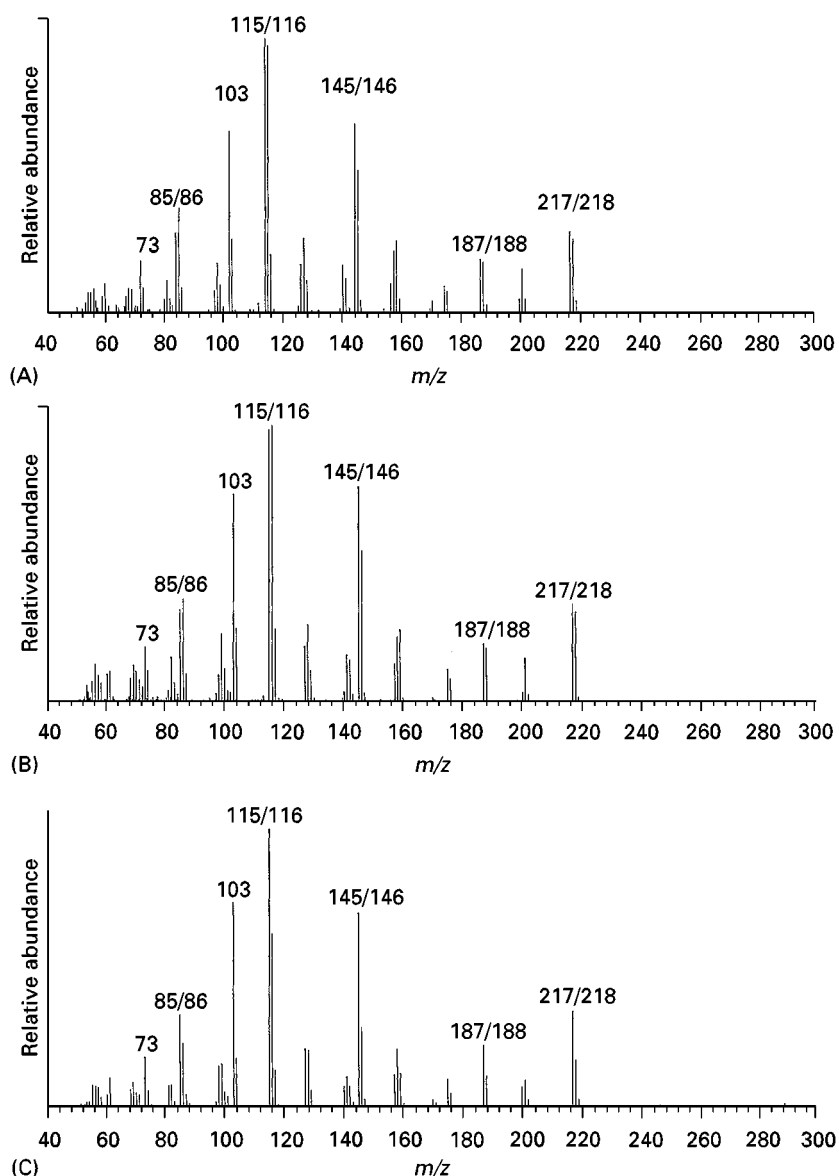

Figure 6 Mass spectra of alditol acetates (A) ribose standard (B) ribose present in hydrolysate of strain 168 (C) a mixture of ribitol and ribose present in hydrolysates of *Bacillus subtilis* W23. Ions derived from the C₁ end are labelled with deuterium (e.g. m/z 146). Ions generated from the C₆ end are not labelled and thus m/z is one less (e.g. m/z 145).

analysis is improved, particularly in product ion spectrum mode. However, in trace quantitative analysis of carbohydrates, in MRM mode, it has been observed that the ion trap is less precise than the triple quadrupole. However, the low cost, ease of use of the ion trap and its power for absolute identification (product ion spectrum) make its use extremely attractive for diagnostic applications.

It is important to note that heavy isotope-labelled internal standards for many sugars are unavailable as pure compounds. Whole ^{13}C -labelled bacterial cell hydrolysates may be used as a cheap alternative source. As an example, in quantitative studies, both methylglucamine and ^{13}C -labelled muramic acid have

been used as internal standards in the analysis of muramic acid (a unique chemical marker for bacteria not found elsewhere in nature). While quantitation is better with the latter, there is a possibility of contamination of the ^{13}C -labelled muramic acid with non-labelled muramic acid. Thus, at the detection limit of the procedure, where the major issue is to prove the presence or absence of muramic acid, methylglucamine is preferred. At higher levels, where quantitation is the major issue, ^{13}C -labelled muramic acid is preferred. Obviously an internal standard with both characteristics would be optimal and this is currently under investigation. Isomuramic acid has been described as a natural component of the

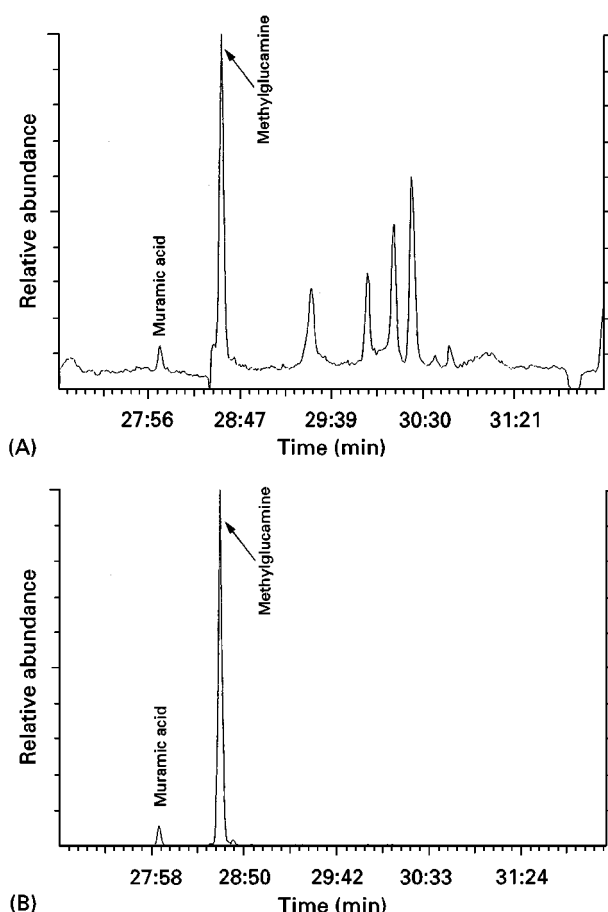

Figure 7 GC-MS-MS shows chromatograms of cerebrospinal fluid from a patient with bacterial meningitis. (A) Full scans (precursor ion m/z 403 for muramic acid and m/z 327 for methylglucamine) would have a similar appearance to a SIM GC-MS chromatogram (m/z 403 and m/z 327 respectively); (B) multiple reaction monitoring (m/z 403 to m/z 198 transition). 250 μ L of cerebrospinal fluid was analysed and found to contain a total of 13.6 ng muramic acid. Methylglucamine 500 ng (internal standard) was present in the sample.

lipopolysaccharide of certain bacteria and also has been chemically synthesized. Whether muramic acid and isomuramic acid can be adequately chromatographically resolved has not yet been addressed.

Application of GC-MS-MS in Trace Analysis

Ion trap GC-MS-MS has been used for absolute identification of trace levels of muramic acid in human body fluids. This is the only report to date using GC-MS-MS to detect muramic acid or any other marker for bacteria in a human/animal body fluid or tissue. Product ion mass spectra (upon MS-MS analysis) of muramic acid peaks (≥ 30 ng mL $^{-1}$) found in infected human body fluids were identical to those of pure muramic acid. An illustration of the detection of muramic acid in human cerebrospinal fluid is shown (approximately 5 ng mL $^{-1}$). A powerful feature of

the ion trap is the utility of the product ion spectrum for absolute identification of trace levels in complex matrices. This is likely to have particular utility for studies of clinical specimens to determine the presence of bacteria (that are difficult to culture) or their nonviable cell wall components (not detectable by culture). Sterile body fluids and tissues from healthy humans or animals do not generally contain muramic acid.

Figure 7 shows GC-MS-MS chromatograms of cerebrospinal fluid from a patient with bacterial meningitis. The full scan (precursor ion m/z 403 from muramic acid and m/z 327 for the internal standard, methylglucamine) would be similar in appearance to a SIM GC-MS chromatogram (m/z 403 and m/z 327 respectively). Muramic acid is readily detected, but there are clearly numerous background peaks, particularly in the m/z 327 window. For comparison, using multiple reaction monitoring (m/z 403 to m/z 198 transition) background peaks are eliminated. The sample contained a total of 13.6 ng of muramic acid. Figure 8, for comparison, shows full scan and MRM

Figure 8 GC-MS-MS chromatograms of uninfected cerebrospinal fluid from a patient with otitis media. (A) Full scan of precursor m/z 403 (equivalent in appearance to SIM GC-MS); (B) multiple reaction monitoring (m/z 403 to m/z 198 transition).

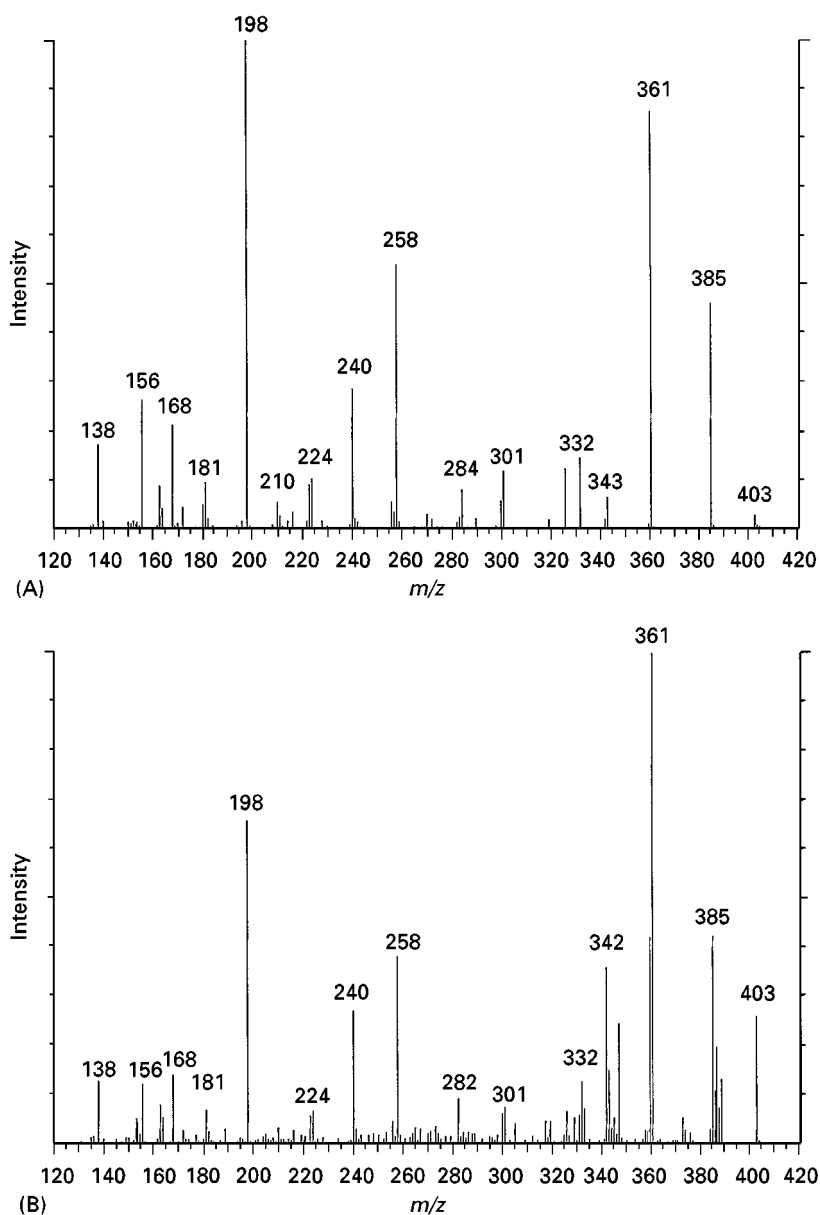

Figure 9 Product ion spectrum (GC-MS-MS) of m/z 403 (A) muramic acid standard (250 ng total) and (B) cerebrospinal fluid from patient with bacterial meningitis (2.7 ng in 400 μ L of cerebrospinal fluid analysed).

of cerebrospinal fluid from a patient with otitis media (inner-ear infection). In this instance, culture indicated the absence of bacteria in the sample. As expected, there is no peak at the retention time of muramic acid; this serves as a negative control.

A product ion spectrum of muramic acid present in a cerebrospinal fluid (2.7 ng total) and a muramic acid standard (250 ng) are compared in **Figure 9**. Muramic acid is clearly categorically identified from the spectrum of the patient's sample, although background ions are obvious. Clearly, this represents an analysis close to the detection limit, for GC-MS-MS of this type of complex biological sample.

MRM analysis has great utility for determining the levels of bacterial contamination for clinical and environmental analyses. For example, muramic acid levels have been demonstrated to serve as a useful measure of biocontamination of air. This has relevance to our understanding of the 'sick building phenomenon' and assessing the quality of indoor air. The product spectrum is of limited use in the analysis of environmental samples, since bacteria are invariably present. However, as noted above, it is a powerful tool for absolute detection of bacteria in human body fluids and tissues which are sterile in the absence of infection.

Gas Chromatography and Liquid Chromatography

In the 1980s successful analysis of underivatized sugars using high performance liquid chromatography was introduced. Eliminating derivatization dramatically reduces sample handling and chemical manipulation. After separation on anion exchange columns (particularly the PA1 column) sugars are detected with a pulsed amperometric detector (PAD). This LC system has been successfully used for the separation and identification of amino, neutral and acidic sugars. Chromatography is performed in concentrated NaOH. At high pH, interaction of ionized hydroxyl groups with the anion exchange resin produces excellent sugar separations. The electrochemical (PAD) detector also detects carbohydrates with excellent sensitivity at alkaline pH. Unfortunately, in the analysis of sugars in complex matrices, the nonselective PAD detector often has inadequate specificity to discriminate sugars of interest from background noise.

When chromatography is performed in conjunction with the mass spectrometer (e.g. GC-MS or LC-MS), the increased selectivity of detection allows analysis of less purified samples. For example, whole cell hydrolysates can be analysed. With LC-PAD analysis, structural components such as glycoproteins or polysaccharides must be purified prior to analysis. LC-MS-MS has been used for quantitation of sugars in complex environmental matrices. LC-MS and LC-MS-MS for the analysis of carbohydrates show great promise but are still in the developmental stage. Currently, GC-MS and GC-MS-MS have considerably lower detection limits than LC-MS and LC-MS-MS. Automation of sugar derivatization for GC eliminates many of the advantages of LC-based techniques over the GC-based ones but the only derivatization procedure for carbohydrate analysis by GC that has been automated, at this time, is the alditol acetate procedure.

Conclusions

GC-MS and GM-MS-MS are mature techniques which may be used in the analysis of carbohydrate monomers in complex samples. In SIM GC-MS and MRM GC-MS-MS, sugars are readily detected and quantitated in complex samples, although use of MRM dramatically lowers the detection limit. Using total ion (MS) and product ion spectra (MS-MS), identification at trace levels is readily performed. The detection limit is much lower for the latter when the ion trap GC-MS-MS is used. Substantial improvements have been made to sample preparation, including simplification and computer-controlled automation of derivatization reactions for GC analysis. This is likely to help GC-based techniques to remain competitive with their LC competitors where derivatization

is usually eliminated. The limit of detection is still currently much lower with GC-based procedures.

Introduction

The development of selective and sensitive methods for analyses for carbohydrates is one of the most challenging areas of analytical chemistry. The main difficulties in the analysis of carbohydrates arise from their considerable number of isomeric forms due to the various possible configurations of the monosaccharides. Oligo- and polysaccharides are composed of different combinations of them, forming linear or branched polymeric species, many of which may differ only in the position of attachment and anomeric configuration of the glycosidic linkages. Moreover, complex carbohydrates can also be characterized by the presence of various nonglycosyl substituents, which include acetyl, pyruvyl, methyl and sulfate esters and ether, amine and phosphate groups. Finally, methods of analysis for carbohydrates require special attention as they play an important role in many diverse research and industrial domains such as biochemistry, clinical chemistry, biology, pharmacy, biotechnology and food science.

Over the last 25 years, high performance liquid chromatography (HPLC) has been the method of choice for the determination of carbohydrate species, and as a result a large number of HPLC methods have been developed to determine a wide variety of carbohydrate samples.

Alkyl or aminoalkyl bonded silica and polymeric phases, protonated or metal-loaded cation exchange resins in conjunction with refractive index (RI) or low wavelength UV detection, as well as high-performance anion exchange chromatography at high pH (HPAEC), coupled with pulsed amperometric detection (PAD) are the methods commonly used. These different approaches are considered in more detail later.

Polar Phases

Polar silica-based packings, as well as unmodified silica are suitable stationary phases for the separation of sugars and other carbohydrates by hydrophilic interaction chromatography (HILIC), a name proposed in 1990 by Alpert to indicate all chromato-

graphic methods driven by polar interactions, which involve partitioning between the more hydrophobic mobile phase and a layer of mobile phase enriched with water and partially immobilized on the stationary phase. Since 1975 aminopropylsiloxane-bonded silica columns have been used widely for this type of chromatography. The fundamental mechanism governing separation of carbohydrates using amino-propylsiloxane-bonded phases is partition between the mobile phase and the water-enriched solvent associated with the stationary phase.

The most common bonded phases are manufactured by reaction of microparticulate silica (having an average particle diameter of 3 or 5 μm) with organosilanes (for example, 3-aminopropyltrimethoxysilane), to form siloxane bonds. Improvements in column efficiency can be achieved using spherical particles of silica gel, which form more homogeneous beds than those obtained employing irregularly shaped particles.

For separations on aminoalkylsiloxane-bonded silica columns, acetonitrile–water mixtures are usually employed as the mobile phase. The proportion of acetonitrile ranges from 80 to 90% by volume for chromatography of sugars and other carbohydrates of low molecular weight. For example, a mobile phase consisting of 85% acetonitrile in water is useful for the separation of monosaccharides. A low percentage of water in the mobile phase is necessary to increase the interactions between sugars and the amino groups bonded to the stationary phase, improving selectivity and monosaccharide separation. On the other hand, 80% acetonitrile in water allows good separation of di- and trisaccharides differing sufficiently in structure, such as sucrose, maltose, lactose and raffinose. For chromatographic analysis of oligosaccharides of degree of polymerization (dp) above 3, mobile phases containing acetonitrile in lower proportions are required. Under these conditions separations are currently carried out at room temperature and with flow rates from 1 to 2 mL min^{-1} . An example of the effective separation of oligosaccharides obtained by lowering the acetonitrile content in the eluent is shown in **Figure 1**, where about 30 distinct peaks of a partial hydrolysate of (1 \rightarrow 4)- α -D-glucan from amylose are separated using a mixture of acetonitrile–water (57 : 43, v/v). Although acetonitrile is the most common organic component of the mobile phase, the use of ethyl acetate, together with acetone or methanol have also been proposed.

Figure 1 Chromatogram of partial hydrolysate of (1 → 4)- α -D-glucan (amylose). Chromatographic conditions: column, ERC-NH-1171 (200 \times 6 mm ID); eluent, acetonitrile–water (57 : 53); flow rate, 1 mL min⁻¹, detector, Shodex RI SE-32 at 1×10^{-5} RI units full scale; temperature ambient. (Reproduced from *Journal of Chromatography* (1985), 321: 151, with the permission of Elsevier Science Publishers.)

Aminopropylsiloxane-bonded silica packings have been widely used in HILIC of sugars and other carbohydrates. However, they have the drawback of limited life, due to the formation of glycosylamines by reaction of the amino groups bonded to the stationary phase with reducing sugars (formation of Schiff's bases). The formation of glycosylamines results in both deactivation of the column and loss of the sugar analytes with an undesirable effect on quantitative analysis. An alternative to the use of these columns is the addition of a small amount (0.01–0.02%, v/v) of a diamino or polyamino compound to the eluent used in HPLC on a silica column, which results in modification of the silica to give it characteristics of an amino propylsiloxane-bonded phase. This approach can be accomplished with various amine modifiers, which must carry at least two amino groups, one being required to bond the modifier to the silica gel via hydrogen bond formation, and one which has to be free to interact with the carbohydrate analytes. Usually *in situ* modified silica columns show a longer life than aminopropylsiloxane-bonded columns, because the amine adsorbed on the silica surface is continuously regenerated by the amine added to the mobile phase. Various polyfunctional amines have been proposed as modifiers, including ethylenediamine, 1,4-diaminobutane, tetraethylenepentamine (TEPA) and piperazine.

Another approach is to replace aminopropylsiloxane-bonded columns with a silica-based packing carrying bonded amide, cyano, diol, polyol or cyclodextrins as alternative stationary phases. These phases have similar selectivity to amino-type phases

and do not form Schiff's bases with reducing sugars. Polymer-based columns have also been proposed, increasing application in HILIC of carbohydrates. Although diol-bonded silica, as well as vinylpyridinium polymers have proven to be capable of greater selectivity in carbohydrate separations, aminopropylsiloxane-bonded columns are the most frequently used in HILIC of carbohydrates. A list of some HPLC columns commonly employed in the HILIC of carbohydrates is given in Table 1.

Cation Exchangers

HPLC analyses of carbohydrates are most frequently carried out on cation exchange stationary phases consisting of sulfonated polymer-based materials, which can be obtained in various degrees of cross-linking and various particle sizes.

Cation exchangers based on poly(styrene-divinylbenzene) (PS-DVB) copolymers are the most common stationary phases used for carbohydrate separations. Copolymer-based columns offer many advantages for the analysis of carbohydrates and alditols. The PS-DVB copolymers exhibit excellent physical strength, pH stability over a wide range and are not easily subjected to degradation by oxidation, hydrolysis or elevated temperature. Carbohydrate separations on column packed with a cation exchanger PS-DVB resin can be affected by the degree of cross-linking and type of counterion.

PS-DVB resins are relatively rigid gel-type media and separation can take place when the analytes penetrate at least partially into the matrix. The lower the cross-linking, the more open the structure and more permeable it is to higher molecular weight carbohydrates. For example, a 4% cross-linked resin is suitable to resolve oligosaccharides of high molecular weight, whereas smaller oligosaccharides can be well resolved on an 8% cross-linked resin.

As mentioned earlier, the selectivity of cation exchange columns depends to a large extent on the ionic form of the packing material. Loading of sulfonated resins with various cations produces substantial changes in retention of neutral carbohydrates in several ways, such as the formation of coordination complexes, ion–dipole interactions, ionic hydration and hydrogen bonding. When the resins are loaded with Ca^{2+} , Ag^+ , Pb^{2+} , La^{3+} , marked differences in the retention and selectivity are observed and the mechanism of retention involves the formation of coordination complexes between the carbohydrates and the fixed-metal ions. However, the separation of oligosaccharides is predominantly governed by size-exclusion mechanisms and oligomers elute in order of decreasing molecular weight. The first systematic

study of the chromatography of sugars and alditols on a cation exchange resin was published in 1975 by Goulding, who showed that the complexing cations Ca^{2+} , Ag^+ , Sr^{2+} , Ba^{2+} and La^{3+} gave longer retention times than the alkali-metal cations. This effect

can be attributed to coordination between the metal ions and -OH groups of sugars and alditols and their retention can be correlated with the ability to form relatively strong chelate complexes of the adjacent hydroxyl groups of sugars and alditols with the fixed

Figure 2 Separation of maltooligosaccharides from dp 14 to dp 2. Chromatographic conditions: column, Rezex RSO-Oligosaccharide (200 × 10 mm ID); mobile phase, water; flow rate, 0.4 mL min⁻¹, temperature, 75°C; detector, RI (with permission of Phenomenex, Torrance, CA, USA).

cation of the resin. For example, stronger binding will occur in sugars where the configuration of the hydroxyl groups at C-1, C-2 and C-3 of the pyranose ring have an axial-equatorial-axial sequence that can form relatively strong tridentate complexes than the binding of sugars, which form complexes with only a pair of axial-equatorial hydroxyl groups. In sulfonated cation-exchange resins carrying Li⁺, Na⁺, and H⁺, there is no evidence that these counterions interact directly with carbohydrates, and their effects can be interpreted simply by ionic hydration. Cation exchange resins carrying calcium ions are the most commonly used for chromatography of sugars allowing good separations of monomeric sugars (pentoses, hexoses), alditols and di-, trisaccharides (Figure 2). Cation exchange resins carrying silver ions give better separation of maltooligosaccharides up to a degree of polymerization of 13 glucose units (see Figure 3).

Carbohydrate separations on cation exchange resins loaded with various metal ions can be carried out with deionized water as the mobile phase. However, when chromatographic runs are performed at room temperature, peaks are broadened or eluted as a doublet owing to the separation of the two anomeric forms of reducing carbohydrates. As is well known, for each of the ring modifications of a free sugar, two isomers (α and β isomers or anomers) can exist, because a new asymmetric centre is created by ring closure at the reducing carbon atom (see Figure 4). The two anomers can be selectively retained on cation exchange resins loaded with various metal ions. For example, when glucose is chromatographed at room temperature on a sulfonated PS-DVB

Figure 3 Separation of monosaccharides and alditols. Chromatographic conditions: column, Rezex RPM-Monosaccharide (300 × 7.0 mm ID); mobile phase, water; flow rate, 0.6 mL min⁻¹, temperature, 75°C; detector, RI (with permission of Phenomenex, Torrance, CA, USA).

resin column in the hydrogen form, the reducing monosaccharide is eluted as a single peak (Figure 5A), whereas with the same column in the calcium form, almost baseline separation of α and β anomers is achieved, indicating that a ligand exchange mechanism is also involved (Figure 5B).

The most common approach to avoid the formation of doublets is to increase column temperature. By heating the HPLC column in the calcium form to 85°C, the rate of interconversion between the α and β anomers of glucose is accelerated, and it is eluted as a single peak. Separations are usually performed with a column temperature ranging from 80 to 85°C, though lower temperatures (65°C) may be used. Higher temperatures give faster diffusion and narrower peaks. Conversely, increasing temperature is normally accompanied by a decrease in retention. Organic modifiers such as acetonitrile may be added to the eluent up to a concentration of 30% (v/v) without causing any damage to the PS-DVB matrix. For example, the addition of acetonitrile increases retention of the analytes and may improve resolution of sugar alcohols.

Sulfonated resins in the protonated form are useful for profiling not only monosaccharides and sugar alcohols, but may be useful for analysis of a wide range of organic acids, alone and in combination with carbohydrates, short-chain alcohols, aldehydes and ketones. Selectivity can be altered by changing the pH as well as the type of mineral acid (H₂SO₄ or HCl at mmol concentration), used as the eluent. Employing these columns, amino sugars may also be separated. Sugars of food interest and sugar alcohols,

Figure 4 Anomeric configurations of D-glucose.

including sorbitol and mannitol may be separated using pure water as the mobile phase. An example is shown in **Figure 6**, where a mixture of lactose, galactose, mannitol, sorbitol and xylitol are separated on a sulfonated cation exchange resin in protonated form. Furthermore, a separation of lactose, glucose and galactose in a lactose-hydrolysed milk sample is shown in **Figure 7**. Both separations were performed by isocratic elution with water at room temperature. Under these conditions sugar alcohols, as well as reducing sugars are eluted as single sharp peaks.

Tables 2 and **3** list some of the commercially available columns containing sulfonated styrene-divinylbenzene resins in various ionic forms.

Anion Exchangers

Anion exchange chromatography is not a technique commonly associated with analysing neutral carbohydrates. It has been shown that the hydroxyl groups in carbohydrates can form reversible anionic complexes with borate, which can be separated on an anion exchange column. However, this technique is not currently applied to HPLC of mono- and oligosaccharides.

Anion exchange chromatography is basic media allows the separation of carbohydrates without addition of any borate to the mobile phase. The pK_a of neutral carbohydrates usually fall in the range of 12–14, and at high pH their hydroxyl groups are either partially or completely ionized, enabling this class of compounds to be separated as anions by high performance anion exchange chromatography (HPAEC). Moreover, alkaline conditions allow the detection of carbohydrates by PAD at a gold electrode. The compatibility of PAD with gradient elution coupled with the high selectivity of specifically tailored anion exchange stationary phases, allows mixtures of underivatized simple sugars, oligo- and polysaccharides to be separated with good resolution in a single run, and quantified down to picomole levels. Under these conditions, separations cannot be performed using classical silica-based columns due to their poor stability at high pH levels. The columns commercially available are packed with polymer-based anion exchangers produced by proprietary manufacturing processes. These packings include electrostatically latex-coated polymer-based anion exchangers and macroporous polymer-based resins functionalized with quaternary ammonium groups, which have unique selectivity for sugar alcohols.

Monosaccharide separations are usually performed under isocratic conditions and the elution order is inversely correlated with pK_a . Alditols are

Figure 6 Separation of (1) lactose, (2) galactose, (3) mannitol, (4) sorbitol and (5) xylitol on a sulfonated cation-exchange resin in the hydrogen form. Chromatographic conditions: column, PL Hi-Plex H ($8\ \mu\text{m}$, $300 \times 7.7\ \text{mm}$ ID Polymer Laboratories Ltd, Shropshire, UK); mobile phase, water; flow rate, $0.4\ \text{mL min}^{-1}$ at room temperature; detector, refractive index detection.

less retained than the corresponding reducing sugars as can be readily understood on the basis of acidity. Since the anomeric hydroxyl group is the most acidic among all the OH groups, replacing it with an ordinary OH group (which is less acidic) would naturally result in less retention. For oligosaccharides, retention increases dramatically with increasing molecular mass. HPAEC, followed by PAD detection, has been found to resolve positional isomers of neutral oligosaccharides, which are defined as having the same number, type, sequence, and anomeric configurations as monosaccharides, but differing in the

linkage position of a single sugar. Correlation of retention times with the structure of different oligosaccharides may suggest that at least two factors are involved in determining the superior resolution of oligosaccharides by HPAEC: the relative acidity of the hydroxyl groups and the accessibility of oxyanions of the saccharides to the functional groups of the stationary phase.

Addition of a modifier, such as sodium acetate, allows the elution of oligosaccharides in more reasonable times. Acetate anion is used as a strong 'pusher' because it offers rapid equilibration, allowing a

faster elution of strongly retained components without compromising selectivity and does not interfere with amperometric detection. **Figure 8** is the chromatogram of a sample of starch hydrolysate containing over 20 linear homologous maltooligosaccharides. The separation was obtained by increasing sodium acetate content in the mobile phase by linear gradient elution. On the other hand, under isocratic

elution, alditols and mono- and disaccharides can be separated in a single run (**Figure 9**).

As has been shown by several authors in comparative studies, the use of HPAEC-PAD for quantification of neutral monosaccharides, aminosaccharides, glucuronic acids, linear and branched oligosaccharides in complex matrices, is usually superior to HPLC-RI and HPLC-UV in terms of sample

preparation and sensitivity. In the last five years many significant developments in carbohydrate analysis by HPAEC-PAD have been reported.

Alkylsilica Packings

Octadecylsiloxane bonded silica materials, usually designed for reversed-phase (RP) chromatography are

nonpolar stationary phases having relatively strong hydrophobic character. The choice of an RP column with pure water as the eluent is an easy method for HPLC analysis of carbohydrates. However, the mechanism governing retention of carbohydrates is not reversed-phase partition but a form of hydrophobic chromatography, involving van der Waals interactions between carbohydrates and the alkyl chains of

Figure 8 Separation of linear maltooligosaccharide oligomers of up to 20 residues. Chromatographic conditions: column, CarboPac PA 100 (250 × 4.0 mm ID) connected to a CarboPac PA 100 guard column (50 × 4.0 mm ID), all from Dionex, Sunnyvale, CA, USA; eluent A, 50 mM sodium acetate in 120 mM sodium hydroxide; eluent B, 300 mM sodium acetate in 120 mM sodium hydroxide; flow rate, 1.0 mL min⁻¹ at room temperature; detector, PED in pulsed amperometric mode. Maltooligosaccharides were eluted by a linear gradient from eluent A to eluent B in 35 minutes. Numbers over peaks indicate dp values.

the bonded phase. The first HPLC separation of carbohydrates employing octadecylsiloxane-bonded silica columns was carried out in 1981 using a DextropakTM (Waters) column specifically developed for the separation of underivatized oligosaccharides. However, separation of monosaccharides was poor. Furthermore, a drawback of the reversed-phase column in carbohydrate separation is the undesired resolution between α and β anomers of the saccharides, which complicates the chromatograms.

Different approaches have been proposed to avoid unwanted double peaks. The most widely used approach is to reduce the oligosaccharide samples with sodium borohydride. In this way for each reducing saccharide the corresponding alditol is eluted as a single peak. As reported earlier, another approach to avoid the formation of doublets is to increase column temperature, which increases the rate of interconversion between the α and β anomers. Cheetham and Teng reported that modification of a Dextropak C₁₈ column by adding nonionic Triton X-100 detergent or tetramethylurea to the eluent, avoids the elution of anomeric doublets. The elution of broad peaks or doublets due to resolution of anomers can be precluded by the addition of triethylamine to the eluent. However, under these conditions, some risk of silica degradation is likely.

This drawback may be overcome by the use of reversed-phase packings obtained by introducing oc-

tadecyl groups into hydrophilic porous polymers having hydroxyl groups on the surface. Koizumi *et al.* have described the use of an AsahipakTM ODP-50 column packed with C₁₈-bonded vinyl alcohol copolymer gel for the separation of glucooligomers, which were selectively eluted as single peaks using sodium hydroxide at pH 11 as the mobile phase. Under these conditions, the rate of interconversion between the α and β anomers of saccharides was accelerated satisfactorily, avoiding the elution of anomeric doublets. The same polymeric column has been used to separate cyclodextrins and branched cyclodextrins. Columns packed with C₁₈-bonded phases have also found application in ion-pair chromatography with tetrabutylammonium in a buffered medium, for analysis of oligosaccharides containing an acid or sulfate group.

Detection

One shortcoming in the HPLC of carbohydrates is the often inadequate sensitivity and selectivity in the detection process, particularly when they are at a much lower concentration than other compounds present in complex matrices. The analysis of neutral carbohydrates is difficult due to their absence of a chromophore. RI detection is the most popular detection technique for carbohydrates in HPLC but a serious drawback is that it can only be used to monitor

Figure 10 Detection of sugars in fruit juices by ELSD. Chromatographic conditions: column, LiChrosorb Diol ($5\ \mu\text{m}$, $250 \times 4.6\ \text{mm ID}$, from Merck); mobile phase, dichloromethane–methanol (82:18 v/v); flow rate, $1\ \text{mL min}^{-1}$ at room temperature; detector, ELSD; evaporator, 50°C ; air inlet pressure, 20 psi. Chromatogram A: fructose ($t_r = 5.95$), glucose ($t_r = 7.85$), sucrose ($t_r = 11.39$) in a blood orange juice. Chromatogram B: fructose ($t_r = 5.93$), glucose ($t_r = 7.82$), sucrose ($t_r = 11.30$) in a grapefruit juice.

isocratic separations. As a substitute for RI, the evaporative light-scattering detector (ELSD) can be used with gradient elution, thus performing better chromatographic separations. In addition, ELSD provides rapid stabilization before operation and improves baseline stability and better sensitivity. The direct detection of analytes is achieved through three consecutive stages, which are independent of each other. The first stage consists in the nebulization of the column effluent with air or nitrogen to produce a finely divided spray, which passes through a heated chamber to vaporize the eluent. During the second stage, solutes less volatile than the eluent create a particle stream that intersects a collimated light beam (mono- or polychromatic, depending on the apparatus design), producing light scattering. The scattered light is then detected by a photomultiplier (or photodiode), where the output is proportional to the amount of solute present over a wide concentration range. Description of the technical performance and configuration of the current commercial ELSD detectors for both HPLC and supercritical fluid chromatography (SFC), have recently been reported by Henry, Dreux *et al.* and Lafosse *et al.* Owing to the nature of light scattering detection, ELSD is especially

suitable for solutes which are characterized by a lower volatility than the eluent used for the chromatographic separation. A wide variety of solvents may be used as eluents; highly volatile mobile phases are preferred either as pure solvents or as a combination of two or more. Nevertheless, carbohydrates are more soluble in water than in organic solvents and therefore water is frequently a constituent of the mobile phase.

By coupling the HPLC system with an ELSD detector, carbohydrate separations on bare silica, as well as diol and polyol, bonded phases can be performed by isocratic or gradient elution from mixtures of dichloromethane–methanol. With these organic eluents, separation of mono-, di- and oligosaccharides can be achieved by gradient elution without baseline drift and with a good sensitivity; an example of the analysis of sugars using a diol silica-based column coupled with ELSD detection is reported in **Figure 10**. Fructose, glucose and sucrose are separated from a blood orange juice and a grapefruit juice using a mixture of dichloromethane–methanol (82:18 v/v) as the mobile phase. The detection limit is 20 ng for all analysed sugars. Furthermore, the stationary phase employed avoided Schiff's base

formation with reducing sugars and periodic regeneration of the column was not needed. The high chemical stability of the column is demonstrated comparing the reproducibility of the retention times reported in chromatogram A with those reported in chromatogram B, which was performed 100 injections apart. The use of ELSD detection is less favourable when employing metal-bearing cation exchange columns, where carbohydrates are eluted with plain water at high temperature (80–95°C). Since these cationic resin–water systems cause an increase in detector noise at the temperature of the separation. On the other hand, Dreux and Lafosse demonstrated the usefulness of ELSD detection in oligosaccharide and polysaccharide analysis obtained on octadecylsiloxane-bonded silica columns with gradient elution at increasing methanol content in water.

Only few carbohydrates exhibit significant absorbance in the low UV, such as acidic disaccharides released from glycosaminoglycans by enzymatic digestion, which carry an unsaturated uronic acid residue at the nonreducing end that enables their UV detection at an absorbance maximum of 232 nm. Neutral carbohydrates can be analysed by UV detection at wavelengths lower than 200 nm but under these conditions they are subject to interference from other compounds with similar absorption properties. Furthermore, in this UV region acetonitrile also absorbs strongly and therefore the UV detector is unsuitable for use in HILIC of underivatized carbohydrates, where separations are usually performed employing mobile phases rich in this solvent. This drawback can be overcome by either pre- or postcolumn derivatization. The most common chemical derivatization methods allow the conversion of carbohydrates into derivatives that can be detected with an online ultraviolet, visible, or fluorimetric detector. Besides an improvement in the detection properties, the chemical reaction can also enhance the selectivity of the total analytical method. For example, pre-column derivatization of oligosaccharides with a hydrophobic chromophore is the most common approach to enhance the resolution and detection of oligosaccharides into their components by RP-HPLC.

A wide variety of methods have been developed for pre- and postcolumn derivatization of carbohydrates. Comparative advantages and disadvantages of these two approaches have been reviewed by Giese and Honda (see Further Reading).

Although prechromatographic and postcolumn chemical derivatization methods allow the conversion of carbohydrates into either photometrically or fluorimetrically active adducts that can be detected with high sensitivity, the simplicity of sensitive direct

detection in HPLC will always be preferred whenever possible.

In HPLC, polar aliphatic compounds containing electroactive groups can be directly detected by pulsed electrochemical detection (PED), a generic term introduced by LaCourse to indicate all detection strategies based on the application of multi-step potential-time waveforms at noble metal electrodes for electrochemical detection.

Amperometric detection is used to measure the current or charge generated by the oxidation or reduction of analytes at the surface of a working electrode in a flow cell. For several classes of molecules, which include carbohydrates and aliphatic alcohols and amines, amperometric detection can only be performed if a repeating sequence of three potentials is applied for specific times to the working electrode. Amperometric detection under the control of a three-step potential-time waveform is known as PAD.

This detection mechanism was first applied in 1981 for the detection of aliphatic alcohols at Pt electrodes and then proposed for the direct determination of carbohydrates when in 1983 Rocklin and Pohl coupled the first commercial detector dedicated to PAD with HPAEC.

In pulsed amperometric detection mode, the working electrode is held at an analytical potential E_1 for a time t_1 . At this potential the CHOH groups of carbohydrates are oxidized. The current is measured at the end of the E_1 pulse to allow the charging current to decay, resulting in more accurate measurement of the electroactive species. If only a single potential is applied, the detector response would steadily decrease as the electrode surface became fouled. The electrode surface is oxidatively cleaned by a positive potential E_2 ($E_2 > E_1$) for a time t_2 . The voltage on the electrode is then reversed to a strongly reducing potential E_3 for a time t_3 to convert the gold oxide layer at the surface of the electrode back to native gold, thus renewing the surface.

Selection of the potentials for detection, cleaning and conditioning are based on current (i)-potential (E) response from cyclic voltammetry (CV) recorded for triangular waveforms ($E - i$). Extensive studies on the optimization of waveforms for pulsed amperometric detection of carbohydrates have been published recently by LaCourse. Carbohydrates can be detected by PAD at Au electrodes in highly alkaline media. For separations which are not carried out under adequately alkaline conditions, as in the analysis of monosaccharides, the detection requirement of a strong alkaline medium can be satisfied by post-column addition of NaOH (generally in the range 300–500 mM) by means of a pump, a hydraulic device, or membrane reactor.

Conclusions: Summary of Main Trends

A wide variety of HPLC methods are available to analyse carbohydrates from various complex matrices. Aminopropylsiloxane-bonded silica of small particle diameter (3 µm), amine-bonded vinyl alcohol copolymer packings, diol- and cyclodextrin-bonded silica, as well as macroporous cross-linked vinylpyridinium polymers, are some of the columns of choice for high selectivity in the HILIC of carbohydrates. Furthermore, a large number of columns may be selected to separate carbohydrates on cation exchange resins carrying different counterions. Employing these columns the chromatographic separation is governed by a combination of size exclusion and ligand exchange mechanisms. In oligosaccharide separations, size exclusion is the primary mechanism which involves the binding of hydroxyl groups of the sugars with the fixed counterion of the resin, thus they elute last.

On the other hand, RP-HPLC with plain water as the eluent may be useful for the separation of various underivatized oligosaccharides. The mechanism governing this HPLC method produces separations that complement those given by cation exchange columns and therefore the two techniques should be used in conjunction in isolation and analysis of carbohydrates.

Column instability and low detection sensitivity are the major disadvantages using these HPLC methods. However, column and detection technologies to analyse carbohydrates are in continuous development.

Mono- and oligosaccharides are detected without any derivatization by PAD, which is sensitive and selective for detection of these analytes. The use of HPAEC is now widely accepted as a powerful analytical tool for carbohydrate analysis. However, HPAEC methods require dedicated columns and instrumentation.

Introduction

Carbohydrates are some of the more difficult compounds to separate from each other. They primarily

differ in the number of carbon atoms, the configuration of the chiral centres and the size of the molecules, that is to say whether they are di-, tri- and oligosaccharides. If two carbohydrates have any one of the three characteristics in common, they can be difficult to separate. There are some carbohydrates that differ by having a special functional group, for example a carboxyl group (giving uronic, onic and aric acids),

an amino or acetyl-amino group (giving amino and *N*-acetyl amino sugars), or a phosphoric acid ester group (giving carbohydrate phosphates). Nevertheless, because carbohydrates play such an important role in living systems and comprise a large number of important naturally occurring products, methods for separating them were some of the earliest chromatographic procedures developed.

Early chromatographic methods in the 1950s for separating carbohydrates used paper as the solid support. In the early 1960s Thoma introduced thin-layer chromatography (TLC) for separating carbohydrates. The use of TLC, however, was not particularly easy and convenient at that time, as each laboratory had to prepare its own thin-layer plates. This led to a wide variation in the quality of the plates and in the results that were obtained, even within a single laboratory. The results were difficult to reproduce from day to day and particularly from laboratory to laboratory. It was not until reproducible thin-layer plates were commercially developed and produced at a reasonable price, primarily by Whatman and Merck in the late 1970s, that TLC became a viable and valuable procedure.

TLC has now become the principal method of choice for the separation of carbohydrates. High performance liquid chromatography (HPLC) has displaced TLC in many laboratories, although for carbohydrates and other materials, TLC is much preferred over HPLC. When compared with HPLC, TLC is much less expensive, easier to perform, uses simple equipment, uses much less sample, and the detection of the carbohydrates directly on the plate is more sensitive. TLC is also more reproducible. With HPLC, once a sample has been added to a column, the column is irreversibly modified. Because of the high cost of the HPLC columns, many hundreds of samples must be separated and analysed in series on the same column to make the procedure economically feasible; whereas sample placed on to a TLC plate is separated in its own little column or lane, which is not affected by other compounds that have previously been adsorbed and separated on the support material. Further, approximately 18 samples can be simultaneously separated on a single 20 × 20 cm TLC plate, which can include standards. A simple comparison of the migration positions with the migration positions of the standards can be used for qualitative identification.

TLC Support Material, Solvents and Detection Methods

The principal support material found most useful for valuable in the separation of carbohydrates is silica

gel, a stable and inert substance. The silica gel thin layer is usually uniformly 250 µm thick over the TLC plate. The resolution of carbohydrates is achieved by the selection of a specific solvent system. Many solvent systems have been empirically developed. The particular solvent used depends on whether the carbohydrates are monosaccharides, disaccharides, trisaccharides or oligosaccharides, or whether they contain a charged group such as a uronic acid, an amino sugar or a carbohydrate phosphate.

A relatively simple solvent that has found valuable use in the separation of a number of mono-, di- and trisaccharides is acetonitrile–water (85 : 15, v/v). This solvent is frequently the first choice when separating unknown carbohydrates in a sample. Solvents for the separation of more complex mixtures can then be developed using other organic compounds in combination with the acetonitrile–water system. Many solvent systems contain three components: water, a water-soluble component and a water-insoluble component. The three components are combined in various proportions so as to give a homogeneous solution. For maximum resolution, the technique of multiple ascents is frequently employed. In this technique, the solvent is allowed to ascend to the top of the TLC plate, whereupon the plate is removed from the developing tank and the solvent is completely evaporated from the plate. The plate is then put back into the TLC tank for a second, third and/or fourth ascent. **Figure 1** illustrates the separation of relatively complex mixtures of carbohydrates using this technique with acetonitrile–water (85 : 15, v/v) solvent.

A very sensitive detection system has recently been developed in which most carbohydrates can be detected in the 50–2000 ng range, directly on the TLC plate. The method uses a detecting reagent, consisting of 0.3% (w/v) of *N*-(1-naphthyl)ethylenediamine and 5% (v/v) concentrated sulfuric acid in methanol. The TLC plate is removed from the developing tank, dried and rapidly dipped into the reagent. The plate is dried and placed in an oven at 120°C for 10 min. Carbohydrates give blue-black spots on a white background. Most carbohydrates can be detected by using this reagent, with the exception of 2-amino-2-deoxy sugars, 2-*N*-acetylamino-2-deoxy sugars and sugar alcohols. This is primarily due to the requirement of forming furfurals from the carbohydrates by dehydration with the sulfuric acid. An older method used sulfuric acid charring, in which a 25% (v/v) solution of sulfuric acid in methanol was sprayed on to the TLC plate, dried and then heated at 120°C for 10 min. This is a much less sensitive method, with detection in the 10–100 µg range. Further, the

Figure 1 Separation of various mono-, di- and trisaccharides on Whatman K5 TLC plates (18.5 cm solvent path length for each ascent), using four ascents of acetonitrile–water in volume proportions of 85 : 15 at 20–22°C. The carbohydrates were detected by using the *N*-(1-naphthyl)ethylenediamine–sulfuric acid–methanol dipping reagent.

spraying technique is much less environmentally friendly than a dipping technique.

The separation of radiolabelled carbohydrates permits several sensitive techniques to be used to detect and quantify the carbohydrates directly on the TLC plate, such as a TLC radioactive scanner or a PhosphoImager. Both can be used to detect and quantitate ^{14}C , ^{35}S , or ^{32}P radioactive isotopes, although the PhosphoImager is several orders of

magnitude more sensitive and relatively easy to use quantitatively.

TLC Separation of Homologous Series of Oligosaccharides

The separation of oligosaccharides is important in a wide variety of applications, such as analysis of carbohydrates in foods, analysis of oligosaccharides from glycoproteins and glycolipids, the analysis of enzymatic synthesis of oligosaccharides and the analysis of the hydrolysis of polysaccharides. Many of these analyses involve the separation of a homologous series of oligosaccharides containing one or possibly two kinds of glycosidic linkages and as many as 20–30 monosaccharide residues of the same type in the oligosaccharides. The separation of a homologous series of saccharides, containing 2–30 monosaccharides residues, linked β -1 \rightarrow 2, β -1 \rightarrow 3, α -1 \rightarrow 4, and α -1 \rightarrow 6, has been reported, using silica-gel plates developed with butanol-1–ethanol–water. The development time was however, several hours for one ascent.

Much faster systems, using Whatman K5 plates or Merck silica gel 60 plates and multiple ascents with acetonitrile–water systems, have been developed for the separation of maltodextrins (α -1 \rightarrow 4 linked glucosaccharides) and isomaltodextrins (α -1 \rightarrow 6 linked glucosaccharides). The separation of maltodextrins was achieved using acetonitrile–ethyl acetate–propanol-1–water in volume proportions of 85 : 20 : 50 : x . The amount of water (x) can be varied from 50 to 70 parts by volume, depending on the desired number of saccharides to be separated. The largest saccharides can have 20 D-glucose residues. Likewise, using up to four ascents can increase the number of saccharides separated. **Figure 2** illustrates the separation of maltodextrins using one to four ascents of 85 : 20 : 50 : 60 volume proportions at 20–22°C.

Isomaltodextrins migrate more slowly than an equivalent maltodextrin mixture, primarily because of differences caused by the α -1 \rightarrow 6 glycosidic linkage vs the α -1 \rightarrow 4 glycosidic linkage. To obtain an equivalent separation for the isomaltodextrins, the water content (x) of the solvent system has to be increased to 90 or 100 volume proportions. **Figure 3** illustrates the separation of isomaltodextrins using one to four ascents of acetonitrile–ethyl acetate–propanol-1–water in the volume proportions of 85 : 20 : 50 : 90 at 20–22°C.

The power of TLC separations of saccharides, using these solvents, is illustrated in **Figure 4** in which complex saccharides are separated from mixtures produced by the action of two different enzymes

Figure 2 Separation of D-glucose and maltodextrins on Whatman K5 TLC plates (18.5 cm solvent path length for each ascent), using 1–4 ascents of acetonitrile–ethyl acetate–propanol-1–water in volume proportions of 85 : 20 : 50 : 60 at 20–22°C. The numbers at the top of each chromatogram indicate the number of solvent ascents. The carbohydrates were detected using the *N*-(1-naphthyl)ethylenediamine–sulfuric acid–methanol dipping reagent. Reproduced with permission from Robyt and Mukerjea (1994).

acting on polysaccharides. The saccharides were separated by using four ascents of acetonitrile–ethyl acetate–propanol-1–water in volume proportions of 85 : 20 : 50 : 50 at 20–22°C on a Whatman K-5 plate. Lane 1 on the plate is a set of maltodextrin standards, containing D-glucose, maltose, maltotriose and so forth down to maltodextrins with 14 D-glucose residues; lane 2 shows an equivalent set of maltodextrin saccharides that were obtained by the action of isoamylase acting on shellfish glycogen; lane 3 shows the separation of products that resulted from the action of porcine pancreatic α -amylase acting on potato amylopectin. Saccharides marked B6, B7 and B8

contain six, seven and eight D-glucose residues, respectively having one α -1 \rightarrow 6 glycosidic linkage and five, six and seven α -1 \rightarrow 4 glycosidic linkages. These saccharides migrate in between the maltodextrins, for example, BB6 migrates behind G6 and faster than G7, B7 migrates behind G7 and faster than G8, and so forth. Saccharides marked BB9, BB10 and BB11 contain nine, 10 and 11 D-glucose residues, respectively, with each having two α -1 \rightarrow 6 glycosidic linkages and seven, eight and nine α -1 \rightarrow 4 glycosidic linkages. Saccharides containing one D-galactose residue will usually migrate more slowly than an equivalent saccharide containing all D-glucose

Figure 3 Separation of D-glucose and isomaltodextrins on Whatman K5 TLC plates (18.5 cm solvent path length for each ascent), using 1–4 ascents of acetonitrile–ethyl acetate–propanol-1–water in volume proportions of 85 : 20 : 50 : 90. The numbers at the top of each chromatogram indicate the number of solvent ascents. The carbohydrates were detected using *N*-(1-naphthyl)ethylenediamine–sulfuric acid–methanol dipping reagent. Reproduced with permission from Robyt and Mukerjea (1994).

Figure 4 Separation of maltodextrins and maltodextrins, containing one and two α -1 \rightarrow 6 linkages. Lane 1, glucose and maltodextrin standards; lane 2, maltodextrins resulting from the action of isoamylase reaction with shellfish glycogen; lane 3, α -amylase action on amylopectin. Whatman K5 TLC plate (18.5 cm solvent path length for each ascent) was irrigated four times with acetonitrile-ethyl acetate-propanol-1-water in volume proportions of 85 : 20 : 50 : 50 at 20–22°C. The carbohydrates were detected using the *N*-(1-naphthyl)ethylenediamine-sulfuric acid-methanol dipping reagent. Reproduced with permission from Robyt and Mukerjea (1994).

residues. Compare the migration of lactose with cellobiose in Figure 1.

To illustrate the tremendous power that TLC has in separating carbohydrate oligosaccharides with very similar structures, **Figure 5A** shows the chromatographic separation of saccharides formed by the action of *Leuconostoc mesenteroides* B-512FM dextransucrase transfer of D-glucose from sucrose to malto-oligosaccharide acceptors having two to eight D-glucose residues. Two different products were formed by the transfer of D-glucose to the reducing end of the acceptor saccharide to form an α -1 \rightarrow 6 linkage (product-1a) and transfer of D-glucose to the non-reducing end of the acceptor saccharide to form α -1 \rightarrow 6 linkage (product-1b). Products 2a, 2b, 3a, 3b and so forth are products resulting from the transfer to C₆ of reducing-end glucose residue and to C₆ of the nonreducing-end glucose residue, and so forth of the first, second and third acceptor products. These complex products were separated using four ascents of ethyl acetate-ethanol-water (2 : 2 : 1, v/v/v) on a Whatman K5 TLC plate.

Figure 5B shows the separation of an even more complex mixture of products, containing the same number of D-glucose residues, but differing from each other by the location of the transferred D-glucose residue and the types of linkages, either α -1 \rightarrow 6 or α -1 \rightarrow 3. D-Glucose was transferred from sucrose to maltotriose by the action of three enzymes (F, I and S). Enzyme I gave four initial products, 1a–1d; 1a had D-glucose transferred to C₆ of the reducing-end glucose residue of maltotriose; 1b had D-glucose transferred to C₆ of the nonreducing-end glucose residue of maltotriose; 1c had D-glucose transferred to C₃ of the reducing-end glucose residue of maltotriose; and 1d had D-glucose transferred to C₃ of the nonreducing-end glucose residue of maltotriose. Enzymes F and S only gave two initial products, 1a and 1b. All three enzymes gave higher products: 2a, 2b, 3a, and so forth.

Separation and Detection of Sugar Alcohols on TLC

One of the more difficult separations of carbohydrates is that of separating aldoses from their corresponding alditols (sugar alcohols). Alditols can be separated from their aldoses on TLC by using two ascents of acetonitrile-ethyl acetate-propanol-1-water in volume proportions of 85 : 20 : 20 : 15. As previously mentioned, alditols are not readily detected by the sulfuric acid-based reagents described above. The best detection system is an alkaline silver nitrate-sodium thiosulfate dipping system that will detect alditols in the range of 500 ng to 1 μ g. The dry TLC plate is dipped into a silver nitrate-acetone

Figure 6 Separation of alditols (sugar alcohols) from their corresponding aldoses on Whatman K5 TLC plates (18.5 cm solvent path length for each ascent) using two ascents of acetonitrile–ethyl acetate–propanol–water in volume proportions of 85 : 20 : 20 : 15 at 20–22°C. The carbohydrates were detected by using the alkaline silver nitrate dipping reagents. Reproduced with permission from Han and Robyt (1998).

Figure 7 Separation of *O*-methylated D-glucoses. Lanes 1 and 3 are standards; lane 2 is the analysis of a complex, highly branched D-glucan. Whatman K6 plates were irrigated (18.5 cm solvent path length for each ascent) at 20–22°C, using two ascents of acetonitrile–chloroform–methanol in volume proportions of 3 : 9 : 1. The carbohydrates were detected by using the *N*-(1-naphthyl)ethylenediamine–sulfuric acid–methanol dipping reagent. Reproduced with permission from Mukerjee *et al.* (1996).

acid hydrolysis. The number of methyl groups and their location on the resulting monosaccharides indicate the positions of the linkages to the monosaccharides in the oligosaccharides or polysaccharides and whether or not the saccharides are branched. For example, if a gluco-polysaccharide contains 1 → 4 glycosidic linkages with 1 → 6 branch linkages, there would be three kinds of methylated monosaccharides: 2,3,6-tri-*O*-methyl-D-glucose (major), 2,3,4,6-tetra-*O*-methyl-D-glucose (minor from the nonreducing-end D-glucose residues) and 2,3-di-*O*-methyl-D-glucose (minor from the branched D-glucose residues). The use of TLC to separate and analyse these methylated monosaccharides has greatly simplified methylation analysis of oligo- and polysaccharides. Further, because of the sensitivity of detecting the methylated monosaccharides (lower limits of 25–50 ng range) directly on the TLC plate, micro amounts of saccharide (10 µg) can be methylated and analysed. **Figure 7** illustrates the chromatography of methylated D-glucoses on Whatman K6 TLC plates, using two ascents of acetonitrile–chloroform–methanol in volume proportions of 3 : 9 : 1 at 20–22°C. The methylated carbohydrates are detected by dipping the plate into the *N*-(1-naphthyl) ethylenediamine–sulfuric acid–methanol reagent described above, followed by heating for 10 min at 120°C.

Quantitative Determination of Carbohydrates

The easiest method of detecting and quantitating carbohydrates on a TLC plate is to use ¹⁴C-labelled

Figure 8 Densitometric scan of TLC number 3 shown in Figure 2, using a Bio-Rad imaging densitometer. The relative weight per cents for each of the carbohydrates are shown at the top of each peak. The first peak is D-glucose, followed by maltodextrins: maltose, maltotriose, maltotetraose, and so forth, down to a maltodextrin with 14 D-glucose residues.

carbohydrates. The radioactivity can be detected and quantitated directly on the plate using a phosphorimager. The use of radioactively labelled carbohydrates, however, is limited to carbohydrates that can be obtained in radioactive form and therefore limited in the kinds of experiments that can be performed. The more usual case is the chromatography of nonlabelled carbohydrates. The detection of carbohydrates on a TLC plate, using a sulfuric acid-based reagent, such as *N*-(1-naphthyl)ethylenediamine reagent described above, can be quantified using a scanning densitometer. Absolute, quantitative amounts can be determined using various amounts of the monosaccharide involved in the saccharides as standards, for example, D-glucose, D-mannose, or

sucrose, and so forth. However, for many purposes, the relative amounts of the individual saccharides in a mixture are sufficient. In this instance, the individual saccharides that are separated in a mixture can be scanned, the densities of the compounds summed and the percentage of the individual compounds computed by dividing the individual densities by the sum of the densities. Figure 8 shows a density scan of chromatogram no. 3 in Figure 2.

Preparative Separation of Carbohydrates Using TLC

By using the same solvent systems as is used in analytical TLC separations, but substituting TLC plates

that have a much thicker silica gel layer (1000–2000 μm), preparative separations of carbohydrates can be obtained. Approximately 25–50 μL of a 20–30 mg sample of a mixture of carbohydrates is streaked along a sample application line, 15 mm above the bottom of a 20 \times 20 cm TLC plate. The plate is developed in the usual way. After development, 15 mm strips are cut off from each end of the chromatogram and dipped into the detecting reagent. The strips are lined up with the plate and the locations of the desired compounds are marked. The silica gel area containing the compound is scraped from the plate into approximately 2 mL of water. The suspension is mixed and the silica gel removed by filtration or centrifugation. The aqueous extract can then be concentrated to dryness by evaporation, and the compound redissolved if necessary.

Points to Consider to Obtain Good Separations

1. A relatively small (1–25 μL) measured amount of sample should be carefully added on to the TLC plate, keeping the size of the spot as small as possible. The use of a microlitre syringe pipette, such as a Hamilton syringe, is desirable. When many samples are to be added to the TLC plate, a multi-spotting instrument can conveniently be used to make very small, uniform spots with a minimum of effort. The multi-spotter is also convenient when a relatively large volume, for example 10–25 μL , of sample is to be added.
2. Be sure that the developing tank is tightly sealed during development (vacuum grease can be used with glass-to-glass surfaces). The solvent and vapour should be in equilibrium before beginning the development.
3. Allow the solvent to ascend to the *top* of the TLC plate to give the maximum path length for the solvent. The old idea that the TLC plate should be removed from the solvent *before* the solvent has reached the top or *just as* the solvent reaches the top of the plate is not valid, if the chamber is tightly sealed. In fact, it is best to allow 5–10 min extra, after the solvent reaches the top of the TLC plate, before removing the plate. This ensures that the plate has been completely saturated with the solvent over the entire surface of the plate.
4. Use no more than 15 mm margin from the bottom of the plate to the point of sample application, so as to give the maximum path length for the solvent. Also, be sure only to use pencil to mark the TLC plates.
5. In multiple ascending chromatography, dry the plates thoroughly between each ascent. The use of

Figure 9 Glass chamber and holder used to dip the TLC plates into the detecting reagent.

a hair-dryer is a fast and convenient method for drying plates.

6. In developing the chromatogram, rapidly and carefully dip the irrigated plate into the detecting reagent to obtain a uniform amount of reagent over the entire plate. The use of a narrow 1.5 \times 22 \times 22 cm glass chamber is convenient for dipping. A stand and a lid have to be fabricated from polypropylene or similar material to hold the chamber (Figure 9).

Conclusions and Future Prospects

TLC has become a powerful analytical tool for separating compounds with very similar chemical and

physical properties, such as carbohydrates. The development of reliable and reproducible commercial TLC plates has placed it at the forefront of separation methods that can be used for both qualitative and quantitative determinations. Further, the use of relatively simple and inexpensive materials permits a wide range of laboratories, from the high-school teaching laboratory to quality control and research laboratories, to analyse and compare compounds easily, quickly and with high sensitivity. The use of relatively inert materials, such as silica gel on glass, allows chemical reactions to be conducted directly on the plate where the compounds have been separated. These reactions provide qualitative identification of the compounds by specific colour production and the quantitative determination of the compounds by the use of scanning densitometry. The latter is particularly important for carbohydrates as they do not lend themselves to the usual physical detection and quantifying methods, such as ultraviolet or visible absorbance, light scattering or refractive index. The development of a wide variety of solvents has also permitted the separation of carbohydrates that differ from each other in subtle aspects of configuration of chiral centres, differences in the kinds of glycosidic linkages present, and differences in the size of the compounds.

Future developments in TLC of carbohydrates may come slowly as much progress has been made in the last 50 years. But, as in most areas of endeavour, need is the necessity of invention. Developments will undoubtedly be made in new solvents that will separate new kinds of mixtures of carbohydrates obtained from natural products and from chemical and enzymatic modification reactions. There will probably be detection methods developed that will give greater sensitivity in the submicro range of carbohydrates on the plate. The latter will then also provide for the development of new physical instrumentation using lasers for scanning density, reflectance and fluorescence in quantifying carbohydrates directly on the plate.

Introduction

Carotenoids are one of the main classes of natural pigments and are found in a large number of fruits and vegetables (oranges, tomatoes, carrots) and in leaves where their presence is masked by chlorophylls until autumn. They are also found in some animal products (eggs, milk) and seafoods. Typically, carotenoids contain eight isoprenoid units bonded such that the units are reversed at the centre of the molecule. With this arrangement, many carotenoids are symmetrical in nature. The pigmentation of these tetraterpenes is a result of the chromophore created by the series of conjugated double bonds. The structural formula of all carotenoids is derived from that of lycopene, starting with different structural modifications which include hydrogenation, cyclization, oxidation or dehydrogenation. The oxygenated derivatives are known as xanthophylls and bear either the epoxy, carbonyl or hydroxy ester functions on their extremity or terminal ring, while the hydrocarbon carotenoids are referred to as carotenes. The structures of some basic carotenoids are given in **Figure 1**.

Carotenoids have been used for many years in the food industry as colouring material. These compounds also have many biochemical roles, including the important functions of light harvesting and photoprotection in photosynthesis. In humans, the primary use of carotenoids, whether taken as carotenoid-containing food or as dietary supplements, is the prevention or correction of vitamin A deficiency. However individual carotenoids are capable of forming different *cis/trans* geometrical isomers and this in turn is known to affect their biochemistry in certain situations. In fresh plant tissue, all the double bonds have the all-*trans* configuration (most stable structural form); however, isomerization to the *cis* configuration results in a loss of nutritional value. Hence the determination of these isomers is necessary for the quality control of fresh foodstuffs in order to assess the pro-vitamin A activity of foods and for the evaluation of the effects on food-processing on fresh-

ness. Feeding studies have also shown that *cis* isomers of β -carotene have lower pro-vitamin A activities when compared to the all-*trans* form. β -Carotene, besides having the highest pro-vitamin A activity of the carotenoids, has also been reported to have anti-neoplastic activity, perhaps due to their antioxidant and free radical quenching activity, not only at the stage of onset of the disease but also on existing tumours. Hence the importance of the constituents, in terms not only of colour but also nutrition, explains why attempts have been made to characterize and determine these pigments which occur together in mixtures that can be resolved only with the mildest and most selective analytical methods. While the existence of carotenes and xanthophylls was known before 1906, it was not until Tswett developed column chromatography that much was known about the carotenoids. Subsequently, chromatographic methods have improved drastically from countercurrent distribution, gas chromatography (GC), thin-layer chromatography, gravity column chromatography through to high performance liquid chromatography (HPLC).

Recently, a number of studies have been performed involving the separation of carotenoids by either supercritical (SFC) or subcritical fluid chromatography, showing that SFC with carbon dioxide as the mobile phase can provide an alternative to the traditional HPLC methods used. A brief history of the SFC of carotenoids up to the present is summarized in **Table 1**. Supercritical fluids have lower viscosities than liquids and thus solute diffusion coefficients are higher than in conventional solvents. Furthermore, the low critical temperature of some fluids enables many heat-sensitive compounds to be separated without degradation. Manipulation of various parameters such as temperature, pressure, mobile phase, modifiers and stationary-phase type makes complex separations possible. These aspects are considered in more detail in subsequent sections.

Effect of Mobile Phase and Modifiers on Carotene Separations

Supercritical CO₂ has been the most commonly used mobile phase in SFC. It is nontoxic and also has a low critical temperature (31°C), which enables the separation of thermally labile compounds such as carotenoids at low column temperatures. Furthermore, it

Figure 1 Chemical structures of some basic carotenoids.

Table 1 Advances in SFC of carotenoid pigments

Date	Development
1968	Separation of α - and β -carotene by packed-column SFC (Giddings <i>et al.</i>)
1983	Separation of lycopene and α - and β -carotene (Gere)
1989	Separation of geometrical isomers of α - and β -carotene by open tubular SFC (Schmitz <i>et al.</i>)
1991	Understanding of the effect of temperature, pressure, modifier and stationary-phase type on carotene separations (Lesellier <i>et al.</i> , Aubert <i>et al.</i>)
1994	Investigation of spectral shifts of carotenoids in supercritical CO ₂ (Hui <i>et al.</i>)

is compatible with a wide range of HPLC and GC detectors. Nitrous oxide exhibits a polarity similar to CO₂ but has only received limited use because of its oxidizing properties. Nevertheless, both of these mobile phases have been investigated with β -carotene as a probe molecule. Interestingly, the retentive properties of the polar amino stationary phase for β -carotene are largely affected by the CO₂ and N₂O mobile phases, in comparison to the nonpolar octadecylsilyl stationary phase, which is not appreciably affected by these mobile phases.

In cases where increased solubilizing power is required to elute components of interest, modifiers have been successfully added to the supercritical fluid. The resulting effect is reduced solute retention, improvement of chromatographic efficiency and, in some cases, altered elution order. One of the advantages of supercritical CO₂ is that it is chemically compatible and miscible with a large number of modifiers. The effects of a range of modifiers – methanol, acetonitrile, tetrahydrofuran, dichloromethane and trichlorotrifluoroethane – on the SFC of carotenes have been studied using binary and ternary mixtures with CO₂ containing 3–20% (v/v) of the modifiers. Addition of each of these modifiers produces a concentration-dependent decrease in the capacity factors (k') of the carotenes. The effectiveness of the modifiers has not been directly correlated with their densities nor with their polarities, and this suggests that specific interactions between the solutes and the modifiers are important.

Minimal retention is obtained with the strongest modifier, dichloromethane, which is closest to the dipole–dipole interaction of Snyder's triangle. Furthermore, increasing the dichloromethane concentration in the CO₂ results in an overall decrease in retention of the carotenes and also a decrease in selectivity, probably due to reduced interactions between the solutes and the stationary phase, as all the carotenes have high affinities for this solvent. A plot of $1/k'$ against modifier concentration is linear for

a mixture of tetrahydrofuran–methanol in CO₂ whereas, for more polar modifiers, the line curves slightly downwards due to increased solvent polarity, which indicates that solute–solvent interactions are important. On the other hand, an exponential curve is observed for the nonpolar modifiers, suggesting that the solubility of the carotenes is enhanced by an amount independent of the concentration of the modifier.

The selectivity between the *trans* and *cis* isomers is unaffected by the modifiers, whereas the selectivity between the α - and β -all-*trans* compounds diminishes with increasing percentage of modifier. With a CO₂–methanol–acetonitrile mixture, the selectivity between *trans* and *cis* isomers falls as the proportion of acetonitrile is increased, for both the α - and β -carotenes. This phenomenon has been used to advantage in optimizing the separation of the components of a carrot extract, as shown in Figure 2. With methanol–carbon dioxide, the peaks were not well resolved; however, replacing some of the methanol with acetonitrile allowed an additional component in the extract to be resolved and eluted before all-*trans* α -carotene.

Effect of Stationary Phase Type on Retention and Selectivity of Carotenoids

Both open tubular and packed columns have been employed in the separation of carotenoids. Several β -carotene isomers have been separated on an SB-Cyanopropyl-25 (25% cyanopropyl–75% methylpolysiloxane) stationary phase employing supercritical CO₂ with 1% ethanol as the mobile phase. Separation of the isomers of α -carotene however requires the use of a SB-cyanopropyl-50 (50% cyanopropyl–50% methylpolysiloxane) stationary phase. A mixture of β -carotene, echinenone, canthaxanthin, astacene and fucoxanthin has also been separated on open tubular columns with cross-linked poly(cyanopropyl)methylsiloxane and Carbowax stationary phases. However, the more polar carotenoids did not elute.

One of the problems with immobilized polar stationary phases in open tubular columns is their instability towards higher concentrations of polar modifiers. Consequently, both polar and nonpolar packed columns have been investigated for SFC of carotenoids. The retention mechanism in normal-phase columns is based on the lattice-fluid model where the important property of the mobile phase in β -carotene retention is absorptivity as well as solubilizing power. Elution of carotenoids from normal-phase alumina and silica particles can be compared to that of normal-phase LC; however, the materials are strong

Figure 2 Separation of a carrot extract by supercritical fluid chromatography using an Ultrabase UB 225 column (250×4.6 mm i.d.); mobile phase, CO_2 -methanol-acetonitrile (85 : 0.75 : 14.25, v/v/v); pressure, 15 MPa; temperature, 22°C ; flow rate, 3.0 mL min^{-1} ; detection, 450 nm. adsorbents and can prove too adsorptive for CO_2 to elute the more polar analytes. The reversed-phase packings modified with C_8 and C_{18} exhibit dipole-dipole interactions from the surface silanols in addition to the desired dispersion characteristics and have been successfully applied to carotenoid analysis.

The retention of β -carotene on octadecylsilyl (ODS) columns is well correlated to its solubility in the mobile phase. Both the type and the percentage carbon loading of the stationary phase influence the separation of the carotenes by SFC. Among factors that determine the performance of a column, such as the shape and size of the particles, the pore size, the specific surface area and the percentage surface coverage, the kind of function that is bonded to the support is particularly important.

The effect of the stationary phase can be evaluated from overall variations in retention factors or from variations in the extent of separation of different pairs or groups of compounds, such as first, α - and β -carotenes (the isomers not being separated) and second, *cis* and *trans* isomers of β -carotene, or *cis/trans* α - and β -carotenes.

The relationship between the retention factor in SFC and carotene solubility in the mobile phase can be given by the following equations (as long as the same kind of fluid is used as a mobile phase):

$$\ln k^R = \ln \phi + \ln C_{\text{st}}^0 + \frac{(\mu_{\text{ss}}^0 - \mu_{\text{st}}^0)}{RT} - \ln S \quad [1]$$

$$S = a_{\text{m}}^{\text{sat}} C_{\text{m}}^0 \quad [2]$$

where ϕ is the volume ratio of the stationary and mobile phases, C_{st}^0 is the standard (surface or volume) concentration in the stationary phase, μ_{ss}^0 is the chemical potential of the pure solid solute at standard pressure, μ_{st}^0 is the chemical potential of the solute in the stationary phase as it moves toward infinite dilution and standard concentration and pressure, $a_{\text{m}}^{\text{sat}}$ is the activity of the solute at saturation in the solvent and C_{m}^0 is the standard concentration of the solute in the mobile phase. The first, second and third terms on the right-hand side of eqn [1] are constant for a particular column, solute and temperature. If the property of the stationary phase is independent of the nature and pressure of the mobile phase, the solute capacity factor is a function of only the solute solubility in the mobile phase, regardless of the kind of solvent.

The effect of the nature of the stationary phase on carotene retention should be more significant in SFC compared with LC because the interaction between a solute and a supercritical fluid is generally small. In fact, some researchers have reported that solute retention in SFC is sensitive to the properties of the stationary phase. Where the stationary phase is prepared with a monofunctional alkylsilane, there is one-to-one bonding between the reagent and the silanol groups, giving a 'brush-type' structure. Di- and trifunctional silanes can bond to more than one silanol group on the silica support, to give essentially the same type of brush-type stationary phases as monofunctional silanes. However, they can also polymerize in the presence of traces of water. Under suitable conditions, a stationary phase can also be prepared in which each alkylsilane that is bonded to the surface of the silica gives rise to an arborescent-polymeric structure that is not brush-like and differs from column packings in which the support

itself is polymeric. Arborescent-polymeric C₁₈-bonded stationary phases appear to be particularly suitable for separating closely related compounds that differ in the degree of planarity of their structures and have successfully been applied to SFC separation of *cis* and *trans* α- and β-carotenes. Table 2 lists the different columns that have been evaluated for their separating capabilities of the different classes of carotenes. Particular attention should be paid to the estimation of the retention (R) factor (*k'*) for the analytes because this parameter characterizes the stationary phase independently of factors such as size and porosity of the column. It has been found that on arborescent-polymeric columns, the separation of α- and β-carotenes is incomplete if the retention (R) factor for α-carotene is below 6. One also needs to be aware that, unlike a polar stationary phase, an ODS stationary phase is not appreciably affected by the nature of the mobile phase and that β-carotene, being much larger than the alkyl chains grafted on the silica surface, is less affected by the residual silanol groups on the silica surfaces.

Effect of Temperature and Pressure on Carotenoid Separations

The solubility of a substance in a supercritical fluid is the sum of two factors: the volatility of the substance (which is a function of temperature) and the solvating effect of the supercritical fluid (which is a function of fluid density). Hence, solubility is controlled experimentally by selecting appropriate temperatures and pressures which are important for controlling retention in SFC. These parameters influence the solvating power, efficiency and selectivity. At constant pressure, an increase in temperature decreases the density and consequently the solvating power. The temperature also influences the diffusion coefficients of the solutes in the supercritical fluid. With increasing temperature, diffusion coefficients increase and higher chromatographic efficiency results. However, one needs to exercise caution in this regard as carotenoids are thermally labile and will decompose at high temperatures. With pure carbon dioxide, the capacity factor (*k^R*) increases in proportion to the temperature

Figure 3 Dependence of k^R values of carotenoids on temperature at constant pressure (25 MPa). Column, Spheri-5 ODS-5A; mobile phase, CO₂-methanol (80 : 20 v/v); flow rate, 3.0 mL min⁻¹; detection, 450 nm. Squares, all-*trans* α -carotene; circles, all-*trans* β -carotene. Reproduced with permission from Aubert *et al.* (1991).

(at constant pressure) and can be explained by the resulting decrease in the density of the mobile phase. On the other hand, as shown in Figure 3, when the carotenoids are eluted with carbon dioxide containing 12% methanol, k^R decreases with increasing temperature between 22 and 55°C, while the resolution between the all-*trans* α - and β -carotenoids decreases as the temperature is increased. Although the optimum temperature for this separation is between 22 and 25°C, and the mobile phase is therefore subcritical, this is of little consequence because there is no discontinuity in the physical properties of the fluid at the critical point.

At constant temperature, an increase in pressure produces an increase in density. Increasing the pressure increases the mobile-phase viscosity, thus decreasing the mass transfer term C and the diffusion coefficient. In SFC, density (or pressure programming) is the primary method for developing separation. It is analogous to temperature programming in GC, and eluent composition programming in LC. Increasing the pressure at constant temperature leads to decreased capacity factors, which can be explained by the enhanced solubility of the solutes with increasing density of the mobile phase. Figure 4 illustrates the dependence of k^R values of carotenoids on pressure at constant temperature. In this work, the pressure was varied between 100 and 250 bar, at 22°C and the capacity factors were observed to decrease less rapidly at pressures above 200 bar. This is probably due to the nonlinearity of the P - T curve of carbon dioxide, which at 22°C becomes less compressible. In practice, it is preferable to avoid working at pressures

Figure 4 Dependence of k^R values of carotenoids on pressure (P) at constant temperature (22°C). Column, Spheri-5 ODS-5A; mobile phase, CO₂-methanol (80 : 20 v/v); flow rate, 3.0 mL min⁻¹; detection, 450 nm. Reproduced with permission from Aubert *et al.* (1991).

where the fluid is very compressible, as the pressure drop along the column is associated with a density gradient and reduced efficiency.

Detectors in SFC with Reference to Carotenoid Analysis

SFC is compatible with a wide range of detection methods. The two basic types of detectors are the ionization detectors and optical detectors. Most commercial open tubular SFC systems provide a flame ionization detector (FID) as standard and it is therefore the most widely used detector for carotenoids. However, detection of carotenoids in supercritical fluids following chromatographic separation has also been achieved using mass spectrometry (MS) and UV/Vis detectors. SFC-MS provides detailed information on the molecular structure of eluted carotenoids and greatly aids peak identifications. Due to the thermal instability of these compounds, 'soft' chemical ionization is recommended. Use of methane as the chemical ionization reagent gas and a low source temperature of 100–120°C results in minimal fragmentation, even for thermally labile carotenoids. For more routine analysis, online UV-Vis monitoring (especially using photodiode array detection) is now the standard procedure for the analysis of carotenoids by HPLC and is the preferred detection system for the SFC analysis of carotenoids, with a number of high pressure, temperature-regulated flow cells being available. The effects of pressure and temperature on the absorption spectra of carotenoids dissolved in supercritical carbon dioxide are discussed in the following section.

Behaviour of Electronic Absorption Spectra in Supercritical CO₂

When using UV-Vis detection for SFC of carotenoids, attention must be paid to spectral shifts that occur in supercritical fluids, in comparison to those measured in liquid solvents. This is particularly relevant as the effect can influence qualitative and quantitative results. The shape of the absorption spectra of all-*trans*- β -carotene, 15-*cis*- β -carotene and the xanthophylls, zeaxanthin, cathaxanthin and astaxanthin, which are nonacidic oxygen derivatives of the carotenes, are similar in both supercritical CO₂ and hexane. The λ_{\max} of the five carotenoids however shifts to a shorter wavelength (hypsochromic shift) in supercritical CO₂. Figure 5 shows the absorption spectra of all-*trans*- β -carotene in supercritical CO₂ and in hexane. Table 3 lists the maximum absorbance wavelength of the selected carotenoids in supercritical CO₂ and in hexane. Due to the relatively low solubilities of the xanthophylls in supercritical CO₂ below 5000 psi pressure, comparison of the spectra has been carried out at 6000 psi and 35°C. While solvent-induced shifts of the visible (¹Bu⁺) spectra of carotenoids in a range of polar and nonpolar organic solvents commonly used for HPLC are well established, changes in the supercritical CO₂ density have also been observed to shift the λ_{\max} . Density is related to both pressure and temperature, hence a change in either of the two variables is known to affect the absorption maxima of carotenoids. An increase in pressure increases the visible λ_{\max} of all-*trans*- β -carotene. Over the pressure range of 1500–6000 psi (at a constant temperature of 35°C), the position of this λ_{\max} shifts 7.0 nm to longer wavelength (430.0 to 437.0 nm) in a nonlinear manner.

The effect of variation in temperature on λ_{\max} has also been assessed in the range 25–50°C at a constant

Table 3 The maximum absorbance wavelength of carotenoids in hexane and in supercritical CO₂ (6000 psi at 35°C)

Carotenoid	λ_{\max} (nm)	
	Hexane	CO ₂
All- <i>trans</i> - β -carotene	450.0	437.0
Lycopene	472.0	456.0
Astaxanthin	474.0	453.0
Canthaxanthin	464.0	452.0
Zeaxanthin	448.0	436.0

pressure of 3000 psi and over this range only a 2.0 nm shift is observed. Thus, changes to both pressure and temperature can induce shifts in the (¹Bu⁺) λ_{\max} of all-*trans*- β -carotene in supercritical CO₂, although the former is much more significant. In addition to the main absorption peak in the visible region, *cis*-isomers of carotenoids exhibit a peak in the UV region, termed the *cis*-peak, which originates from the ¹Ag⁺ transition. The electronic absorption spectrum of 15-*cis*- β -carotene in supercritical CO₂ shows a clear *cis*-peak in the region 250–350 nm. Unlike the behaviour of the main λ_{\max} in the visible region, the position of the *cis*-peak maxima does not alter as a function of temperature and pressure, but remains fixed, suggesting that the energies of the ¹Bu⁺ and ¹Ag⁺ states of carotenoids may not respond in the same manner to alternations in density.

Future Developments

As SFC continues to evolve, it will probably be increasingly applied to carotenoid analysis, particularly in view of the thermal instability of these compounds. Development of more selective stationary phases and application of micro-packed columns for SFC are key areas where improvements are likely. Micro-packed columns with internal diameters of 200–400 μ m offer increased efficiencies, shorter run times and increased ease of interfacing with ionization detectors. Further, mobile phases such as the fluoro-carbons have shown potential in similar applications and are therefore likely to be investigated for SFC of carotenoids.

Introduction

Catalysis is a branch of chemical kinetics of great industrial and commercial importance. Heterogeneous catalysts are certain particulate solids of high surface area ($1\text{--}300\text{ m}^2\text{ g}^{-1}$) that increase the rates of attaining equilibria. This is achieved by the temporary attachment of reactant molecules by moderate chemical bonds to active sites on their surfaces. Catalysts themselves are not consumed during the process, although their activity is eventually lost by surface degradation. Over 90% of the world's manufactured chemicals involve catalysis at one or more stages. The market is about $\text{£}7 \times 10^9$ per annum, with £200 return on each pound spent on a catalyst.

Background to Heterogeneous Catalysis and Contributions from Gas Chromatography

The invention of gas chromatography (GC) in 1952 and its development since then have been widely reviewed. Before looking at the applications of GC to catalysis, it is necessary to summarize the major stages in the concepts of catalysis and the often independent technological achievements of industrial

scientists and engineers. Tables 1 and 2, respectively, contain the important concepts and terms and the major technical advances in catalysis.

Catalysis has a much longer history than GC – indeed life itself may originate from the catalysed conversion of the primitive atmosphere into bioorganic molecules on the surfaces of clay minerals. The ancients used enzymatic catalysts unknowingly in fermentation to make wine and vinegar. It is salutary that these natural catalysts far outperform any of our synthetic catalysts at ambient pressures and temperatures. Silver, regarded for at least three millennia as having preservative and curative powers and long used for storing wines and wound treatments, has now re-emerged in the sterile surface coating, Amenitrop, whose active antibacterial and antiviral ingredients are silver thiosulfate complexes.

In catalysis empirical technology and industrial innovation have almost always outpaced scientific theory and understanding, but this is less so today; exceptions include the Haber process for ammonia production. Nevertheless, it has always been true that basic studies provide the intellectual framework and accelerate technical developments, i.e. they 'catalyse' progress!

The scientific study of catalysis started soon after the beginnings of chemistry and at the time when phlogiston theory still held some sway. In 1835 Berzelius coined the term 'catalysis' (which is Greek for *to loosen*) after realizing that research findings in the first decades of the nineteenth century demonstrated

Table 1 Terms and characteristics used in catalysis

Term	Characteristics
Heterogeneous catalysts	Large surface area solids that accelerate the rate of attaining equilibrium; they are themselves chemically unchanged by the reaction and therefore do not affect the final equilibrium yields
Active sites	Those unique sites on the surface where the catalytic event takes place. They are usually the steps, edges and kinks of the flat unreactive terraces, and often represent only a few percent of the total surface atoms. Interestingly, catalysis is chemistry at imperfections and discontinuities.
Specific activity	Rate of reaction per unit area of catalyst under standard reactant concentrations. Activity is sometimes defined empirically by the temperature needed for a reaction to reach an arbitrary rate of conversion.
Turnover frequency (TOF)	Number of product molecules formed per second per active site (10^{-2} to 10^2 s $^{-1}$ for synthetic catalysts, compared with 10^3 to 10^7 for enzymes).
Structure sensitive/insensitive reactions	Rate dependent on particle size and crystal face/rate invariant to size and face.
Selectivity	The fraction of reacted molecules converted to a desired product
Durability	How long the catalyst remains active

the accelerating effects of small amounts of materials that themselves were chemically unchanged by the reaction. He is sometimes erroneously quoted as suggesting an almost occult catalytic force, whereas in fact he clearly stated the new 'force' is 'a manifestation of the electrochemical affinities of matter' Michael Faraday had a clear concept of catalysis in 1834 even before Berzelius' presentation of the term to the Swedish Academy of Sciences. It is tempting to associate the discovery of catalysts with the alchemists vain search for the philosopher's stone to transmute base metals into gold; in some respects the traces of 'catalyst stone', which transform 'useless' raw materials into useful products, are more valuable than a stone for making ornamental gold. The appellation 'black art' still lingers, perhaps with some justification, since most industrial catalysts are still formulated by recipes that are incompletely understood and retain an aura of mystery.

The burgeoning nineteenth century chemical industry quickly appreciated the utility and exploitability of catalysts and the lead chamber and contact processes developed rapidly, as did the hydrogenated hardening of vegetable oils and the synthesis of indigo. Perhaps the most important catalyst ever developed, because it averted world famine, was that for the high pressure synthesis of ammonia by Fritz Haber in 1909, and its commercialization by Badische Aniline and Sodafabrik. The technical development of the iron catalyst, which remains largely unchanged, exemplifies the rewards of painstaking research, a full appreciation of thermodynamics and the courage to build large scale industrial plants operating at the then unprecedented pressure of 300 atmos-

pheres at 450°C. The process is a *tour de force* of chemical engineering linked with outstanding science.

The molecular understanding of catalysis really begins in the twentieth century, as have the majority of the catalysts and processes now in use. This is especially true of the petroleum and petrochemical industry, which in the 1960s and 1970s had annual growth rates of 15%. The outstanding development in the interwar years was the Houdry process for the catalytic cracking of heavy petroleum fractions into volatile gasoline components (C₂–C₁₃). The immediate postwar period saw developments such as: (1) platforming catalysts for upgrading gasoline research octane numbers (RONs) by isomerization of straight into branched alkanes and the dehydrogenation of cyclohexanes to aromatics; and (2) steam reforming of methane, naphtha and fuel oil feedstocks into synthesis gas, a carbon monoxide/hydrogen mixture important for ammonia and methane production. The recent development of vehicle exhaust catalytic converters based on rhodium-promoted platinum–alumina for converting carbon monoxide, nitrogen oxides and unburnt hydrocarbons into harmless products is a remarkable achievement for catalysis science, especially in view of the varying gas compositions and temperatures that have to be sustained.

The realization by Langmuir that catalysis involved short-range chemical bonds, which dictated that reactions occurred in surface monolayers, and Taylor's suggestion that catalysis occurred only at unique active sites, together with the discovery of the importance of atomic clusters with specific geometric arrangements by Balandin, were seminal to the growing

Table 2 Important stages and concepts in heterogeneous catalysis

Date	Event
The beginning!	Life originates on the surfaces of clay minerals
Prehistory	Enzymes for making wine and vinegar, sterile silver
1834/1835	Berzelius coins the term catalysis Faraday appreciates the occurrence of catalysis
1830–80	Industrial: H ₂ SO ₄ by lead chamber, contact catalysts; synthetic dyes by mercury catalysis; hardening of oils
1900	Start of modern kinetics by Bodenstein and Ostwald
1900–14	Gasification of coal; syn-gas manufacture
1909	Haber's catalytic synthesis of ammonia
1918	Langmuir's monolayer and Rideal Ely mechanisms
1920s →	Petroleum industry: continuous processing; catalytic cracking; platforming catalysts
1923	Fischer–Tropsch hydrocarbons from syn-gas
1925	Taylor proposes catalysis occurs only at active sites
1925–36	Houdry catalytic cracking process to increase octane number of gasoline
1929	Balandin's proposal of catalysis on multiplet sites
1938	Brunauer–Emmet–Teller (BET) adsorption isotherm
1939–45	Synthetic substitutes for natural products like rubber
1941	Use of oriented metal films by Beeck and Schwab
1941	Fluidized-bed technology
1950–1970s	Explosive growth of the petrochemical industry
1952	Gas chromatography introduced
1955	Zeigler Natta stereoregular polymerization catalysts
1955	Sasol gasification of coal in South Africa
1956	Gas chromatographic reactors introduced
1960	Steam reforming of methane and naphtha to synthesize gas for ammonia and methanol manufacture
1964	Oxychlorination to make vinyl chloride monomer
1965	Microcatalytic chromatographic reactor introduced
1965	Sohio process for acrylonitrile and acrylic acid
1970 →	Surface science studies of surface–substrate intermediates and surface atom arrangements and restructuring
1976 →	Catalytic converters for exhausts emission control
1985 → 1990s	Control of and blending of refinery streams by GC Improvements in exhaust catalytic converters Development of catalytic power generators Hygiene catalysts: sterile coatings, oven cleaning ICI Hydcat process for hypochlorite removal from waste streams Immobilized enzymes – pharmaceutical production Zeolites and aluminium phosphate (ALPO) catalysts developed

detailed understanding, as were the applications of the absolute theory of reaction rates.

Outline of Conventional GC in Catalysis Research

Since many of the developments in catalysis listed in Table 2 predate the invention of GC in 1952, its contributions have inevitably been since then. However, all the important characteristics of catalysts defined in Table 1 require analysis of complex gas mixtures. Thus inevitably the use of this powerful analytical technique in catalyst research is now endemic and pervasive; so much so that it is now used almost routinely in catalyst laboratories and on catalyst testing rigs. It is the technique *sine qua non* for multicomponent analysis, especially when allied to mass spectrometry and spectroscopic methods. It has revolutionized the analysis of complex volatiles in the same way that liquid and paper chromatography have caused a sea change in the analysis of complex involatile bioorganic molecules. It has replaced previous tedious and time-consuming methods such as fractional distillation, which have largely been abandoned since its advent (but see later for a discussion of the online infrared methods now in an advanced state of development). The complex nature of catalysis product streams is illustrated by the chromatograph of a gasoline in Figure 1.

The acceleration of reaction rates by catalysts arises because of the lowering of the energy barriers through the formation of surface compounds. The energy released by the making of surface bonds facilitates the scission or rearrangement of bonds in the substrate molecule, as depicted in Figure 2. The surface bonds must be of intermediate strength; if they are too strong permanent bonding to the surface occurs, and if they are too weak the perturbations are too small. This gives rise to an optimum value of the enthalpy of formation of the surface intermediate and the so-called 'volcano' plots when catalyst activity is plotted against bond enthalpy.

GC cannot give direct information about these crucial surface intermediates, although ingenious experiments using radiolabelling experiments and normal kinetic analysis and numerical modelling can lead to information about their nature. Major advances in surface spectroscopic techniques have occurred since the 1960s allow the observation and quantitation of minuscule amounts (10^{-3} monolayers) of stable and metastable surface species.

However, there has sometimes been a short-sighted overemphasis of the results of these powerful and expensive techniques and a neglect of those from cheaper methods of final product analysis such as GC.

Figure 1 Chromatogram of a gasoline fraction (courtesy of Dr R. Malpas, Shell Research Ltd, Thornton Research and Technology, Centre).

There is the danger that the moieties seen by surface spectroscopies are mere spectators and not the active participants. Prudent researchers interlink surface science results with those from stable final product time profiles and conventional rate studies on the same catalyst. This problem has been highlighted in an elegant demonstration that the rates of ethene hydrogenation were invariant to the levels of the much studied surface ethylidenes. This underlines the essential importance of stable product analytical methods in catalyst research and evaluation. These are integral components for the study of catalysis in

the multifarious reactor types in use, namely: batch, continuous stirred tank slurry, fixed and fluid bed, trickle bed, catalytic gauze and spinning basket.

The high sensitivity of GC (detection limits of 0.1 to 1 ppm) enables very low conversions to be studied. This reduces the problems of poisoning by products of secondary reactions. GC is used routinely and extensively in laboratory research to find new catalysts and processes for existing and new products. It is also used in all the scale-up stages to full plant operation. The output of the plant is constantly monitored by GC and other methods of analysis and the results used to trim operating conditions to meet product specifications when there are changes in feedstock composition, flow rates, and reactor temperatures and pressures.

Conventional reactor studies can be readily automated by using multiple sample loop valves activated by signals from minicomputers, which also acquire and process the compositional data and GC conditions in digital modes. A semiautomatic pulsed small reactor system with a simple timing device for sampling at prescribed times and early data acquisition and processing methods was described as early as 1960.

A commercial laboratory rig incorporating GC is now marketed for catalytic studies at pressures of several hundred atmospheres and temperatures up to 350°C (Chemical Data Systems, Pittsburgh, USA). The pulse of products from the high pressure micro-reactor is depressurized in a multiple loop valve so that its pressure is compatible with that of the carrier gas stream into which it is injected. The unit is

Figure 2 Energy diagram for a reaction occurring homogeneously and heterogeneously.

semiautomatic and data acquisition, processing and control is by a personal computer (PC).

The very ease of using GC routinely often means that the technique is not mentioned in the title of research papers in the open literature, in much the same way that the use of NMR is often assumed and not noted in papers on synthetic organic chemistry. Perusal of recent issues of journals such as the *Journal of Catalysis* and the *Journal of Applied Catalysis* indicate that about 40% have used GC for product analysis, while a BIDS search of the years 1991–97 shows the linking of GC with catalysis in about 90 papers each year.

It is worth emphasizing that process improvement is more common than purposeful or serendipitous invention and discovery. This is because large companies prefer to expand and advance by steady or even marginal changes associated with low risk rather than to initiate new high risk processes requiring large capital investment and many years of negative cash flows and long payback periods. An example is hydrocracking, which was not considered worthwhile by most of the oil companies until Chevron (California, USA) brought the first hydrocracking plant on stream in the mid-1960s – competition is as much the mother of invention as necessity! The scale of operations provides the motivation for marginal improvements; a catalyst that increases the yields of a product by 1% can earn £1 million per annum if product turnover is £100 million p.a. It is in such marginal improvements that GC can prove so valuable because of the ease of measuring such small changes in product yields.

GC has played a role in the development of devices to protect the environment from the complex chemical wastes from the chemical semiconductor and electroplating industries. It was used in the development of the remarkable ‘three-way’ catalytic converter fitted into motor vehicle exhausts. The simultaneous oxidation of carbon monoxide and unburnt hydrocarbons alongside the reduction of nitric oxide in the same catalyst bed exposed to widely different exhaust compositions and temperatures from ambient to 1000°C is a major chemical and engineering achievement. Even the humble kitchen stove has been rendered self-cleaning by incorporating manganese dioxide/zeolites/ferrites into its glass enamel coatings. The application of catalysis and GC in environmental protection is increasing in importance.

Microcatalytic Chromatographic Technique

The microreactor is probably the most direct link between GC and catalysis and has been widely used

Figure 3 Schematic of a microcatalytic chromatographic reactor. TCD, thermal conductivity detector.

for catalyst research since it was first described in 1955. A schematic of the system is shown in **Figure 3**. The principle of this ‘one shot’ technique is simple. A small catalytic reactor is placed as near as possible to the entrance of a GC column. Small pulses of reactant are injected into an inert or reactive carrier gas stream just before the reactor. Reaction takes place in the catalyst bed and the unconverted reactant pulse together with volatile products are swept into the GC column where the components are separated in the usual way and then detected by a rapid response microthermal conductivity detector. A useful adjunct, employed even in the earliest studies, is to place a Geiger detector in the exit stream from the thermal conductivity detector so that the radioactivity of each peak can be determined. This extends the method to include tracer experiments using ^{14}C - and tritium-labelled compounds. The advantages and disadvantages of the microreactor are listed below.

Advantages

1. Rapid surveys of new or modified catalyst are possible, enabling rapid assessment of whether the changes in catalyst formulations have been beneficial or detrimental (but see item 6 below). The rate of acquisition of results ultimately depends on the speed of analysis; because of its relatively slow speed, the interval between successive pulses can be tens of minutes in packed columns but less

in the high speed wall coated open-tubular columns (WOTC) now available.

2. The high sensitivity of GC enables very small reactant pulses to be used with a consequent reduction in the risk of poisoning active sites by trace impurities.
3. Radioactive tracer experiments are straightforward, enabling the path of individual reaction sites in reactant molecules to be tracked into the product molecules.
4. By careful analysis of the changes in product yields with changes in flow rate (contact time) and sample size, the rate expression of the reaction can be established and rate constants and Arrhenius parameters estimated (but see Disadvantage 2).
5. The technique is particularly well suited for kinetic isotope experiments. Alternate pulses of a deuterated and protonated reactant can be injected into the microreactor so that their reactions are compared on exactly the same catalyst sample under identical conditions. Very accurate measures of primary and secondary kinetic isotope effects (the ratio k_D/k_H) can be obtained and subtle mechanistic detail unravelled.
6. Poisoning effects can sometimes be monitored if the activity of the catalyst is found to diminish with successive pulses, an aspect that can be enhanced by using longer contact times or larger pulses.
7. The developments in data acquisition, storage and processing, coupled together with the use of highly reproducible and readily automated loop sampling valves, benefit and facilitate the use of the microcatalytic reactor for mechanistic and kinetic studies and for catalyst screening.

Disadvantages

1. Steady-state conditions are often not achieved in the short contact times used in microreactors. This can be useful for kinetic studies, but is a disadvantage for screening tests of a new catalyst or a new formulation since the catalyst will usually operate commercially in a continuous flow configuration, where steady-state or pseudo steady-state conditions prevail.
2. Accurate measures of the residence time of the reactant pulse in the catalyst bed are essential for reliable kinetic measurements. The time cannot be calculated simply from the outlet gas volumetric flow rate and the bed volume because of the considerable pressure drop between the reactor and the end of the GC column, which varies with flow rate. The corrected residence time t_r is determined from the following equation derived by application of the gas laws to the exiting carrier gas flow

rate:

$$t_r = \frac{2aL}{3V_0} \frac{P_r T_0}{P_0 T_r} \frac{(P_i/P_r)^{3/2} - 1}{(P_i/P_r)^2 - 1}$$

where L is the reactor length and a its cross-section; V_0 , P_0 and T_0 are the volume flow rate, pressure and temperature at the end of the GC column; P_i and P_r are the pressures at the inlet and outlet of the reactor.

Nonlinear first-order plots result if the uncorrected residence time is used, whereas excellent linearity is obtained by using corrected residence times.

3. If the carrier gas is itself a reactant, its depletion in the gas pulse leaving the reactor can result in artefacts because of changes in detector sensitivity when the pulse components pass through the detector. This can be avoided by split stream techniques. In microreactor studies of the dehydrochlorination of 1,2-dichloroethane, air was used as the carrier gas to eliminate the build-up of carbonaceous poisons when inert carrier gases were used. The problem of different amounts of oxygen feeding into the flame ionization detector (FID) flame at different flow rates was overcome by splitting the stream leaving the GC column, so that the air supply to the flame could be held constant by venting different amounts of excess air through a control valve in the column exit stream. Peak broadening and overlapping occurs in the catalyst bed and in the dead volume between the end of the reactor and the beginning of the GC column, leading inevitably to some loss of resolution.
4. The data obtained are inherently integral despite the small contact times used, so that the technique is not readily adapted to give differential reaction kinetics.
5. Most catalyst laboratories will probably use microcatalytic chromatographic reactors in the near to medium-term future, especially since high speed numerical computer methods are now available to model the differential equations of flow and reaction in these reactors. These results place rigorous and stringent tests on the reaction mechanisms proposed and reliable estimates of rate parameters for some of the rate-determining steps can result. These numerical modelling techniques are much better than the use of the approximate though complicated rate expressions, which contain functions of many rate parameters often conjoined and requiring much ingenuity and chemical intuition to untwine. However, the necessity for intricate valving, pressure and temperature corrections, and computer control and data acquisition

and processing, leads to a loss of the essential simplicity of the microreactor technique. These elaborations may lead researchers into using conventional catalytic reactors with proscribed switching of the reacted gas streams into multi-loop sampling valves linked to GC and GC-MS analysers.

Chromatographic Catalytic Reactors (CCR): the Use of Fluid Logic Modules

A GC catalytic reactor deliberately combines the chromatographic separation of components with a catalytic function in the same reactor bed. The technique, first described in 1956, is a variant of the microcatalytic reactor just discussed. The reactor, in conjunction with pulse techniques, can be used for yield enhancement by displacing equilibria and for preserving primary products from secondary reactions with one of the reactants. The yields of primary products from a conventional catalytic reactor are ultimately limited, either thermodynamically through the value of the equilibrium constant, or kinetically by consumption of primary products, which often react more rapidly with one of the reactants, such as oxygen, than does the other reactant, such as an alkene or alkane. Both these limitations can be avoided in a chromatographic catalytic reactor (CCR). The equilibrium limitation arises because the catalyst accelerates the second-order back-reactions as much as it does the forward reaction. The back-reactions may be minimized by chromatographically separating the products from each other. **Figure 4** illustrate the case for the simple equilibrium, $A = B + C$. The back-reaction can only occur in the initial regions of the column where there is overlap between the B and C peaks. If the bed is long enough, then complete conversion of A into B and C is possible. The laws of thermodynamics are not broken because the equilibrium limitation is circumvented by an energy input to

maintain the gas flow and peak separation. By CCR it has been possible to achieve virtually complete dehydrogenation of cyclohexane to benzene at temperatures where the equilibrium constant was $10^{-3} \text{ mol L}^{-1}$. The yields of useful primary products such as alcohols and epoxides are often low because of their rapid secondary reactions. The secondary reactions can be reduced chromatographically by holding back the primary product on the catalyst surface while the reactant pulse rapidly sweeps down the column because of its lower retention. **Figure 5** illustrates the simplified situation for the reaction sequence given below:

The occurrence of reaction [II] can be reduced by rapid separation of the reactant pulse containing oxygen from the ROH formed and retained in the catalytic chromatographic column. By using a silica-supported silver oxide CCR, large quantities of crotonaldehyde have been preserved in the catalytic oxidation of but-1-ene. The lifting of both the thermodynamic and kinetic limitations is enhanced by using narrow injected pulses. Injectors based on fluid logic modules, which have no moving parts and none of the intrinsic delays of actuating the opening and closing of solenoid valves, are ideal for this task and have previously been used for fast GC analysis. Pulses down to 10 ms have been generated and further reductions are possible.

Process Monitoring and Control

The wealth of detail given by GC about the composition of streams leaving reactors and purification units such as distillation columns can, in principle, be used for manual, semiautomatic or fully automatic process

Figure 4 Illustration of how the equilibrium, $A \rightarrow B + C$, is displaced in a GCC reactor.

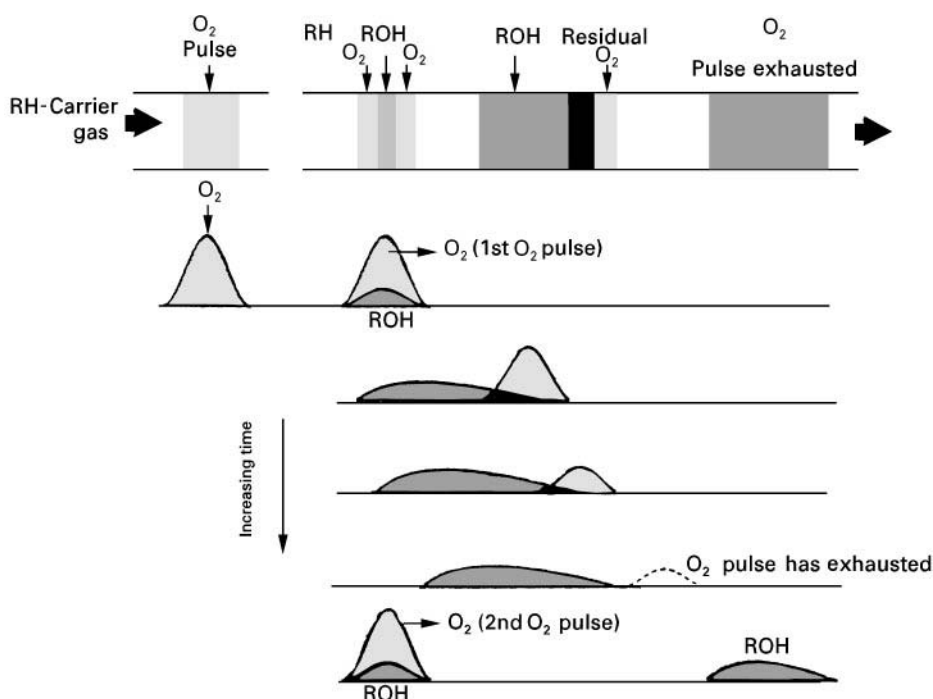

Figure 5 Illustration of how a primary product, ROH, is preserved from secondary reactions with oxygen in a GCR.

control. Automatic GC has been applied to determine gasoline components and a linear algorithm has been developed relating Reid vapour pressures, boiling points and ASTM distillation curves to component indices with good correlations and repeatability. The method has been developed further to enable the RON of a gasoline to be determined automatically by GC analysis with a standard deviation of only 0.09 for RON values in the range 90 to 100. The method has not yet been taken to the point of closing a control loop so that a reactor or a distillation column is controlled by GC, although this closure is feasible.

GC suffers as the control element because of the time needed for analysis. The response time of the plant must be longer than the time for analysis, which is usually tens of minutes, and there is a clear need to develop faster GC based on short narrow-bore open-tubular columns and variants. It is relevant that a method called the 'optical octane dipstick' is now being used in many refineries. This uses a nondispersive near-infrared analyser (NIR) to determine the absorbance at five wavelengths. Apparently a very good measure of RON is obtained from an algorithm linking these absorbencies to ASTM/RONs determined in a standard Petter engine. Clearly this spectroscopic method is faster than GC but can only be used for a narrow range of RONs and composition. The more detailed compositional description by GC analysis could outweigh its present relative slowness. The NIR control units already in use pave the way

forward by posing a challenge to the analyst to speed up chromatographic methods. If the challenge can be met, then the closing of control loops for catalytic reactors based on GC will follow.

Current Trends and Future Prospects

Table 3 lists some of the recent developments that are close to commercial realization together with more speculative, but possible, advances in the new millennium. GC will play an important part in the catalyst

Table 3 Current trends and future prospects

Gas turbines for electricity generation powered by catalytic combustion of natural gas and biomass
Better electrochemical catalysts with high durability for fuel cells based on methanol and eventually hydrocarbons
Production of propene oxide by the catalytic partial oxidation of propene
Home and hospital hygiene based on catalyst-containing surface coatings
Treatment of commercial and domestic waste
Search for power generation from renewable resources and sunlight-activated catalytic dissociation of water into hydrogen and oxygen
Enzymes immobilized on rugged supports may provide ways of fixing nitrogen at ambient temperatures and also of achieving commercial chiral synthesis
Closing of control loops for catalytic reactors, distillation columns, etc., based on GC analysis of product streams and neural control networks

theories and technologies that will be needed to bring these ideas to fruition. The tasks are challenging, even formidable, and require the commitment of scientists and engineers as well as the provision of vast funds for research, development and capital investment by governments and industry.

Copyright © 2000 Academic Press

The first experiments with magnetic separation of cells date from the 1950s when lymphocytes were magnetically separated after *in vitro* phagocytosis of iron granules. The real boom in the application of magnetic labels for cell isolation came in the 1980s and since then an enormous amount of work has been done in both the development and application of this technique.

Magnetic separation of cells has several advantages in comparison with other techniques. In general, the magnetic separation procedure is gentle, facilitating the rapid handling of delicate cells in an unfriendly environment. It permits the cells of interest to be isolated directly from crude samples such as blood, bone marrow, tissue homogenates, stools, food, cultivation media, soil and water. The cells isolated by magnetic separation are usually pure, viable and unaltered. Magnetic separation is a simple, fast and

efficient procedure and the whole separation process can be performed in the same tube. Large differences between magnetic permeabilities of the magnetic and nonmagnetic materials can be exploited in developing highly selective separation methods. The separation procedure can easily be scaled up if large quantities of living cells are required.

Principles of Magnetic Separation of Cells

Two types of magnetic separation can be distinguished when working with cells. In the first type, cells to be separated demonstrate sufficient intrinsic magnetic moment so that magnetic separations can be performed without any modification. There are only two types of such cells in nature: magnetotactic bacteria containing small magnetic particles within their cells and red blood cells (erythrocytes) containing high concentrations of paramagnetic haemoglobin. In the second type, cells of interest have to be tagged by a magnetic label to achieve the required contrast in magnetic susceptibility between the labelled and unlabelled cells. The attachment of magnetic labels is usually attained by the use of affinity ligands of various types, which can interact with target structures on the cell surface. Usually antibodies

microbial pathogens) and parasitology (isolation and detection of protozoan parasites). No doubt many new processes and applications in other fields of biosciences and biotechnologies will be developed in the near future.

Introduction

Analysis and sorting of living cells and purification of cell organelles are important procedures in the life sciences. There is a wide range of techniques and methodologies available, which can be divided into three main groups. The techniques in the first groups are based on physical criteria such as species size, density and shape, and include centrifugation, elutriation and field flow fractionation. Those in the second group are linked to cell surface characteristics, while flow cytometry techniques make up the third group. At a fundamental level, field flow fractionation (FFF) exploits the physical characteristics of the cells or cell organelles. However, cells or cell organelles exhibit some specific characteristics that can be described by a multipolydispersity matrix. The different physical characteristics of these biological materials require different FFF techniques and modes of operation. Special care must be taken if biological integrity and viability are to be preserved.

Specific Cell Characteristics

Cellular materials range in size from 1 µm to 50 µm. Cell populations are classified by a set of morphological, functional and biophysical characteristics. The biophysical characteristics are of particular interest in FFF. Usually, separations in FFF are influenced (but not directed) by surface properties of the sample components (to avoid particle–particle or particle–separator interactions). These properties can be modulated by the use of appropriate carrier-phase modifiers (surfactants). In terms of FFF separations, mass, size and density appear to be the major first order parameters. However, size is generally defined by the radius or the diameter of a sphere whose volume is identical to that of the cell. Size can therefore be deduced accurately if the cell of interest is perfectly spherical. However, this is not usually the case, and the sphericity index, I , is then used:

$$I = \frac{4.84(V^{2/3})}{S}$$

In this equation V is the cell volume and S is its surface area can be difficult to determine. In terms of cell population, these dimensions are averages and should be associated with a variance. These general

considerations are also valid for cell density. Each measurable cell characteristic is therefore associated with an average value and its related variance. A probe of this 'diversity' is of great significance, even in a highly purified cell population. Polydispersity is historically defined in polymer chemistry as the ratio of the percentage of the standard deviation to the average value.

Any cell population can therefore be described by a set of values (average, variance) that leads to a polydispersity index. Cells are different from polymers in that each measurable characteristic of a cell can be associated with polydispersity, so polydispersity can apply to mass, size, volume or density. This matrix of parameters (average, variance) can be used to define a 'multipolydispersity matrix'. The dimensions of the multipolydispersity index depend on the information available. For example, the human normal red blood cell (HNRBC) is the best known cellular material. Its average volume has been measured as 95 ± 5 fL, and its surface area has been calculated as 138.0 ± 5 μm^2 . The HNRBC is known for its discoid shape, which generates other measurable dimensions. Its average diameter is 8.1 ± 0.43 μm , and minimum and maximum thicknesses of 1.0 ± 0.3 μm and 2.4 ± 0.15 μm have been measured. An average sphericity index of 0.77 has been calculated. The density was found to vary from 1.035 to 1.102, with an average value of 1.051. Using these data, it is possible to describe the HNRBC population using a preliminary multipolydispersity matrix, as shown in Table 1.

More complex properties such as cell/nucleus ratio or surface electric charge density (ζ potential, used for dielectric cell purification) can later be added to this basic matrix. In FFF, the sample (i.e. cell surface) characteristics are most important in the development of any separation process. The separator material is chosen so as to avoid or limit particle-separator interactions, which can lead to limited recovery and viability, separator ageing or poisoning. In this domain a general set of empirical rules emerged. If the cell surface is hydrophilic (blood and yeast cells) a hydrophobic material should be used for the separator. The lower the surface energy of the cell, the less non-specific cell-separator interactions occurred, and vice

versa. The interactions between the environmental material and the cells can now be assessed by the general 'biocompatibility' rules.

However the HNRBC population found in circulating blood is not a homogenous, and contains red blood cells (RBCs) of different ages. This suggests that a morphologically homogenous population can be considered to contain different sub-populations. An HNRBC suspension contains cells of equal volume, and cells of equal density, shape or mass. This complex definition of 'population' characteristics is described in Figure 1A. If a set of common parameters is defined, the HNRBCs that meet these limitations may represent only a minor proportion of the whole population. By considering some aspects of this multipolydispersity matrix, rules for cell separation based on biophysical characteristics can be found. Figure 1B shows a three-dimensional graphical representation of the multipolydispersity of the circulating blood cells (platelets, HNRBC, lymphocytes, monocytes, granulocytes) based on the characteristics of size and density. It is obvious that if a size driven cell separation technology could be used, all these populations could be isolated. An isolation technique based only on density would be more complex, as some blood cell population densities overlap. However a size and density driven separation (whose balance has not so far been assessed) would allow selective isolation.

FFF Techniques for Cell Separations

The Different Techniques

The requirements of different fields have led to a wide variety of FFF techniques. Four major technologies have emerged. The first uses fields generated by gravity, either simple earth gravity or centrifugally generated multigravitational fields. It is now generically described as sedimentation FFF (SdFFF for multigravity fields and GFFF for gravity induced fields). The basic technology is the same, although a more complex instrumental design is required for SdFFF, as shown in Figure 2A and B. However, the very simple GFFF designs and procedures can be upgraded for SdFFF separations. This group was historically the most successful in biological applications. Channel cleaning, decontamination and sterilization procedures are common and can be performed simply, as described later. There are many channel wall materials available, and a wide diversity of sample injection technologies or procedures.

The second group encompasses fields generated by a flow, where the accumulation wall is made of a semipermeable membrane of adapted cut-off. This

Table 1 Multipolydispersity matrix for HNRBC

	Average	Standard deviation	Polydispersity (%)
Volume (fL)	95	5	10
Density	1.051	0.08	3
Sphericity	0.77	0.15	11

Figure 1 Multipolydispersity matrix. (A) The definition of a homogenous population is complex. A cell population with homogenous morphological characteristics is actually a complex mixture of sub-populations with different biophysical characteristics. (B) Three-dimensional plot of circulating blood cells (normalized dimensions) as a function of size and density (from bibliographic data). Red blood cells and lymphocytes have the closest characteristics.

Figure 2 The different FFF techniques. (A) Gravitational FFF device; (B) Sedimentation FFF device; (C) symmetrical flow FFF device; (D) asymmetrical flow FFF device; (E) experimental layout of DEP-GFFF device; (F) schematic view of SPLITT-FFF device. 1, Channel wall (accumulation wall); 2, Mylar® spacers; 3, semipermeable membrane (accumulation wall); 4, frit; 5, interdigitated electrode; 6, power amplifier and source of signal; a, inlet (sample and carrier phase); b, outlet (to detector and fraction collection); a' and b', secondary inlet and outlet.

group is of interest because of the possibility of separating species by buoyancy (particle suspension and carrier phase with identical density), such as cell organelles or macromolecules. Two flow-generated FFF techniques were developed. Symmetrical flow FFF (FFFF) uses two independent flows, one to create the external field and the second to sweep the species along the channel (Figure 2C). Asymmetrical flow FFF (AFFFF) uses the same flow along and across the channel, as shown in Figure 2D. However, sample injection procedures are more limited and complex membrane-sample interactions may occur. Fortunately, the wide range of membranes available has made the technique very versatile. The in-channel pressure needed to create the transverse flow-generated field by means of off-channel restrictors has led to rather sophisticated fraction collection devices.

The third group uses electric fields either as the main transverse field (electric FFF) or as dielectric fields combined with gravity (DEP-GFFF) to obtain a hyperlayer focusing elution mode, as shown in Figure 2E. The fourth group encompasses continuous separation devices based on the general SPLITT concept, as shown in Figure 2F.

General Features Linked to Cell Elution Process

The osmotic and pH properties of the biological media must be preserved. Buffer solutions of known pH and ionic strength are used. For example the classical isotonic phosphate buffered saline (PBS) solution. Compared with other FFF elution carried phases, only limited surfactants can be used. Sucrose solution and albumin are both possibilities, the latter being the most versatile carrier phase modifier, usually at a concentration of 0.1% (v/w). The surfactant effect of albumin limits particle-particle interactions as well as particle-wall ones. Albumin adsorption occurs, on relatively hydrophobic channel wall materials, leading to channel ageing or poisoning. Rigorous cleaning and channel regeneration procedures are therefore recommended.

As the general purpose of cell elution in FFF is to limit particle-wall interactions, the commonly used 'stop flow injection procedure' can cause problems. The procedure involves injecting sample at the inlet of the channel in the absence of a flowing stream but while an external field is applied. The species are concentrated near the accumulation wall at the beginning of the channel. The procedure is essential if species are eluted according to the 'Brownian' elution mode, but this is not the case for cells. With cells the risk of generating particle-particle or particle-wall interactions is increased. Specific instrumental modifications of the inlet geometry (directly on the accumulation wall) or low flow-injection procedures will

limit the risk. However, flow injections may enhance selectivity because of the different speeds at which sample components reach the steric hyperlayer focused position in the channel thickness. Elution of cellular material in a steric mode is associated with reduced recovery and possibly with reduced selectivity. Examples of the steric hyperlayer elution mode of HNRBCs and duracytes are given in Figure 3.

Cell Elution Methodology and Detection

Decontamination and Sterilization of FFF Separator

This is necessary to prevent bacterial contamination, but the use of sodium azide should be avoided as it is a cellular toxic. Safe and effective decontamination processes can be considered as an additional step in the cleaning procedure.

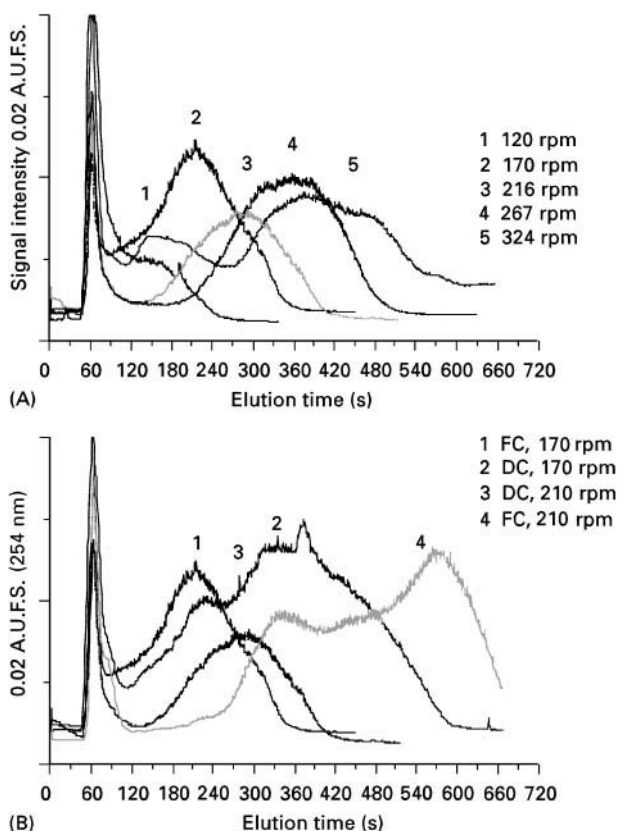

Figure 3 Red blood cells with different elution characteristics in sedimentation field flow fractionation. (A) Fractograms (elution signal) of fresh RBCs. Channel walls made of hydrophobic materials, channel dimensions 0.5 cm wide, 0.025 cm thick, 58 cm long. The channel distance from rotor axis, 10.7 cm. Photometric detection at 254 nm. Sample injection in the established flow (flow rate of 0.5 mL min⁻¹). (B) Fractograms showing retention differences between fresh RBCs and duracytes. RBCs and duracytes are similar in size, but duracytes are rigid fixed RBCs of higher density. FC, fresh red blood cell; DC, duracytes.

The cleaning procedure involves flushing the channel (ten times the void volume) with a hypo-osmotic carrier phase to destroy the cells, then with a classical deproteinization agent (ten times the void volume) to desorb and destroy the cell and surfactant proteins adsorbed in the FFF separator. Finally the system is flushed again with the hypo-osmotic carrier phase.

Decontamination is performed by allowing a hypochloride solution (3–6°C) to flow through the whole FFF system. The volume used should be three to four times the void volume of the FFF device. Prior to injection the channel should be flushed with ethanol and rinsed with the sterile mobile phase. Decontamination and sterilization can be simultaneous if a 5°C hypochloride solution is used with a 70°C ethanol solution.

Cell Detection, Viability and Recovery

At the outlet of the channel it is necessary to obtain eluted material that retains its integrity, that is the diagnosis of the whole particle. Photometric devices operated in the light scattering mode can be used to follow elution. After fraction collection off-line analyses methods such as microscopy, granulometric or flow cytometry analyses are recommended. Cell specific staining is also possible. Cell viability can be diagnosed by means of specific tests, and recovery must also be clearly defined.

Conclusions

The choice of FFF separation techniques for purification of cell or cell organelle populations is influenced by their possible elution modes. Micron sized species eluted under the steric hyperlayer model can be separated using sedimentation techniques if their density differs from that of the carrier phase medium. This is also possible for 'nonbuoyant' sub-micron sized cell organelle species eluted according to the 'Brownian' elution mode.

If species are to be separated according to their size, FFF techniques that use a flow generated external field are preferred. If differences in surface characteristics are important, electrical-based FFF techniques

should be chosen. For large sample volume preparations, SPLIT techniques are useful, whatever the external field. The major technical goal in cell separation is not the set-up of the separator, but the construction of a chain of knowledge. The separator is designed according to the sample characteristics as well as the mode of operation. Cleaning and sterilization procedures, and detection and viability procedures, are linked to the nature of the material to be purified. This 'biotechnological' process is of major importance for FFF separations in the life sciences.

CATALYST STUDIES: CHROMATOGRAPHY

Isolation: Magnetic Techniques

I. Šafařík and M. Šafaříková, Institute of Landscape Ecology, Academy of Sciences, České Budějovice, Czech Republic

Copyright © 2000 Academic Press

The first experiments with magnetic separation of cells date from the 1950s when lymphocytes were magnetically separated after *in vitro* phagocytosis of iron granules. The real boom in the application of magnetic labels for cell isolation came in the 1980s and since then an enormous amount of work has been done in both the development and application of this technique.

Magnetic separation of cells has several advantages in comparison with other techniques. In general, the magnetic separation procedure is gentle, facilitating the rapid handling of delicate cells in an unfriendly environment. It permits the cells of interest to be isolated directly from crude samples such as blood, bone marrow, tissue homogenates, stools, food, cultivation media, soil and water. The cells isolated by magnetic separation are usually pure, viable and unaltered. Magnetic separation is a simple, fast and

efficient procedure and the whole separation process can be performed in the same tube. Large differences between magnetic permeabilities of the magnetic and nonmagnetic materials can be exploited in developing highly selective separation methods. The separation procedure can easily be scaled up if large quantities of living cells are required.

Principles of Magnetic Separation of Cells

Two types of magnetic separation can be distinguished when working with cells. In the first type, cells to be separated demonstrate sufficient intrinsic magnetic moment so that magnetic separations can be performed without any modification. There are only two types of such cells in nature: magnetotactic bacteria containing small magnetic particles within their cells and red blood cells (erythrocytes) containing high concentrations of paramagnetic haemoglobin. In the second type, cells of interest have to be tagged by a magnetic label to achieve the required contrast in magnetic susceptibility between the labelled and unlabelled cells. The attachment of magnetic labels is usually attained by the use of affinity ligands of various types, which can interact with target structures on the cell surface. Usually antibodies

against specific cells surface epitopes are used, but other specific ligands can also be employed. The newly formed complexes have magnetic properties and can be manipulated using an appropriate magnetic separator.

The magnetic separation process for the purification of target cells usually consists of the following three fundamentals steps:

1. The suspension containing cells of interest is mixed with magnetic labels. Incubation time is usually not longer than 30–60 min. Then the magnetic complex formed is separated using a magnetic separator and the supernatant is discarded or used for another application.
2. The magnetic complex is washed several times to remove unwanted contaminants. The selected cells with attached magnetic labels can be used directly, e.g. for cultivation experiments. Alternatively, cells can be disrupted and the cell content analysed using various methods.
3. If necessary, a variety of detachment procedures can be used to remove the magnetic labels from the separated cells. After detachment, the magnetic label is removed from the suspension in a separator and free cells are ready for further applications and analyses.

Necessary Equipment

Magnetic labels and magnetic separators are necessary to be able to perform efficient cell separation. Typical examples are given below.

Magnetic Labels

With the exception of erythrocytes and magnetotactic bacteria, the cells to be isolated have to be magnetically labelled in order to be amenable to magnetic treatment. Magnetic labelling can be performed with magnetic and superparamagnetic particles (*c.* 1 μm and more in diameter), magnetic colloids (*c.* 50–200 nm), magnetoliposomes or with molecular magnetic labels. In most cases the magnetic properties of the labels are caused by the presence of small particles of magnetite (Fe_3O_4) or maghemite ($\gamma\text{-Fe}_2\text{O}_3$); in some cases, chromium dioxide particles or ferrite particles have been used.

Magnetic and superparamagnetic particles Magnetic and superparamagnetic particles (typical diameter *c.* 1–5 μm) attached to the target cells can easily be removed from a suspension with a simple magnetic separator. Since there is usually no magnetic re-

manence the particles are not attracted to each other and therefore they can be easily suspended into a homogeneous mixture in the absence of any external magnetic field. Magnetic particles typically comprise fine grains of iron oxides dispersed throughout the interior of a polymer particle (in many cases of a monosized type), the surface chemistry of which can be modified to provide a range of different linking methods. Alternatively, silanized particles of magnetic iron oxides or magnetic porous glass can be used for the same purpose.

A number of particulate magnetic labels can be purchased commercially. Up to now, in most applications, monosized polymer particles marketed as Dynabeads (Dynal, Oslo, Norway) in various forms have been used. Dynabeads are prepared from monosized macroporous polystyrene particles which are magnetized by an *in situ* formation of ferromagnetic material inside the pores. Other commercially available magnetic particles can be successfully used for cell separation. A selection of these products can be found in Table 1.

Colloidal magnetic labels Colloidal magnetic labels (typical size *c.* 50–200 nm) are prepared by a variety of methods which result in flocks composed of polymer (typically dextran, starch or protein) and magnetite and/or other iron oxide crystals. A standard procedure for the synthesis of superparamagnetic dextran nanospheres is performed by precipitation of iron oxide in the presence of the polysaccharide. To such materials, ligands (usually antibodies, lectins, streptavidin or biotin) are coupled so they can be used for cell separation. Using high gradient magnetic columns, the labelled cells are easily separated. Magnetic particles isolated from magnetotactic bacteria (50–100 nm) composed of magnetite covered by a stable lipid membrane can also be used successfully.

Magnetoliposomes Magnetoliposomes are magnetic derivatives of ordinary liposomes prepared by incorporation of colloidal magnetic particles into the lipid vesicles. When magnetoliposomes are associated with antibodies they can label and/or selectively concentrate the target cells.

Molecular magnetic labels Molecular magnetic labels are usually lanthanides (especially erbium), ferritin and magnetoferritin. Erbium in the form of erbium chloride (ErCl_3) has been used for magnetic labelling of a variety of cells. Different Er^{3+} binding sites, such as carboxyl groups in glycoproteins or the Ca^{2+} receptor sites on the cell wall are responsible for the binding of erbium ions.

Table 1 Selected examples of commercially available magnetic particles and colloidal magnetic labels used or usable for magnetic separation of cells

Name	Diameter (μm)	Polymer composition/surface modification	End groups and activation possibility	Immobilized compounds	Manufacturer/supplier

Ferritin is a naturally occurring, soluble iron storage protein in mammals. For magnetic modification of cells cationized horse spleen ferritin (ferritin coupled with *N,N*-dimethyl-1,3-propanediamine) exhibiting a net positive charge at pH 7.5 is usually used. Under these conditions the cationized ferritin readily forms ionic bonds with the anionic sites on the

cell membrane. Magnetic derivatives of ferritin called magnetoferritin, prepared by controlled reconstitution conditions, have also been used for cell labelling.

Magnetic Separators

A variety of magnetic separators is available on the market, starting with very simple concentrators for

one test tube and ending with complicated fully automated devices. In many cases, especially when working with larger labels, very cheap home-made magnetic separators can be used successfully.

Batch magnetic separators Batch magnetic separators are usually made from strong rare-earth permanent magnets embedded in disinfectant-proof material. The racks are designed to hold various sizes and numbers of tubes. Some of the separators have a removable magnet plate to facilitate easy washing of magnetic particles (**Figure 1**). Test tube magnetic separators enable separation of magnetic particles from volumes ranging between about 5 μL and 50 mL. It is also possible to separate cells from the wells of standard microtitration plates. Magnetic complexes from larger volumes of suspensions (up to approximately 500–1000 mL) can be separated using flat magnetic separators. More sophisticated magnetic separators are available, e.g. those based on the quadrupole and hexapole magnetic configuration.

Flow-through magnetic separators Flow-through magnetic separators are characterized by the flow of the liquid and suspended cells through the separation system. These systems are usually more expensive and more complicated in comparison with batch separators, but for preliminary experiments simple devices can also be used.

Laboratory-scale high gradient magnetic separators (HGMS; **Figure 2**) are composed of small columns loosely packed with fine magnetic-grade stainless steel wool which are placed between the poles of strong permanent magnets or electromagnets. Magnetically labelled cells are pumped through the column, labelled cells are retained on the steel wool, the field is removed and cells are retrieved by flow and usually by gentle vibration of the column. Automation of the separation process has led to the develop-

ment of computer-controlled magnetic cell sorters, such as CliniMACS (**Figure 3**) and AutoMACS, both produced by Miltenyi Biotec, Germany.

Figure 3 (See Colour Plate 65). Computer-controlled magnetic cell sorter CliniMACS. Courtesy of Miltenyi Biotec, Bergisch Gladbach, Germany.

Figure 4 (See Colour Plate 66). The Isolex 300i Cell Selection System. Courtesy of Nexell Therapeutics, USA.

A continuous magnetic sorter based on an electrophoresis counter-flow chamber has been developed. The injected magnetic particles are deviated in the inhomogeneous magnetic field and focused into a stream that is completely separated from the streams of the undeviated particles.

The Isolex 300i Magnetic Cell Separator, produced by Nexell Therapeutics, USA, is intended for the isolation of stem cells from blood or bone marrow. The whole process is done automatically and the device represents a flexible platform for future applications in cell separation (Figure 4).

Procedures for Performing Magnetic Separation of Cells

Magnetic separation of cells is usually performed in one of the following formats:

1. Direct method. The affinity ligand is coupled to the magnetic particles, which are then added directly to the cell sample. During incubation the magnetic particles will bind the target cells which can be then recovered using a magnet.
2. Indirect method. Target cells are first sensitized with a suitable primary affinity ligand. After incubation, excess unbound affinity ligand is removed by washing the cells and then magnetic particles with an immobilized secondary affinity ligand with affinity for the first ligand are added. The magnetic particles will bind the target cells, which can then be recovered using a magnetic separator.

Another differentiation of magnetic separation techniques is based on the selection of the magnetically labelled cells.

1. Negative selection. Negative selection is a method by which a cellular subset is purified by removing all other cell types from the sample. Both the direct and indirect method are applied for negative selection. The advantage is that the purification process does not involve any direct contact of magnetic labels with the cells to be isolated.
2. Positive selection. The target cells are isolated from the cell suspension. Both the direct and indirect method can be used. The separated magnetically labelled cell complexes can be further characterized directly, but in many cases it is necessary to remove larger magnetic particles from the positively selected cells after their isolation.
3. Depletion of cells. Depletion is a method by which one or more unwanted cellular subsets is removed from a cell suspension. Both the direct and the indirect procedure can be applied for this purpose.

Immunomagnetic Separation

Immunomagnetic separation (IMS) is the most often used approach for the isolation of cells. Most often, a monoclonal antibody is used for IMS, but also polyclonal antibodies are used successfully. IMS can be performed in all the formats mentioned above.

In the direct method the appropriate antibody is coupled to the magnetic particles and colloids, which are then added directly to the sample. Ideally, the antibody should be oriented with its Fc part towards the magnetic particle so that the Fab region is pointing outwards from the particle. Several procedures are available for direct binding of antibodies (Table 2).

The indirect method is also used very often. The cell suspension is first incubated with primary antibodies which bind to the target cells. Not only purified primary antibodies have to be used, crude antibody preparations or serum can also be used. After incubation, the unbound antibodies are usually removed by washing. Then magnetic particles with immobilized secondary antibody are added to bind the labelled cells. Target cells – primary antibody complexes – can be also captured by protein A or protein G immobilized on magnetic carriers. Alternatively, biotinylated or fluorescein-labelled primary antibodies and magnetic particles with immobilized streptavidin or anti-fluorescein antibody are used to capture the target cells.

The indirect method is generally more efficient in removing target cells from a suspension because free antibodies will find their target antigen more easily

Table 2 Selected procedures for binding of antibodies on magnetic particles and colloids

Adsorption of antibodies on hydrophobic magnetic particles (especially those made of polystyrene)
Covalent binding of antibodies on activated magnetic particles (e.g. tosyl-activated), or on magnetic particles carrying appropriate functional groups (e.g. carboxy, amino, hydroxy, hydrazide) using standard immobilization procedures
Immobilization of secondary antibodies (i.e. antibodies against primary antibodies) on magnetic particles followed by binding of primary antibodies
Immobilization of biotinylated antibodies on magnetic carriers with immobilized streptavidin
Immobilization of antibodies on magnetic particles with immobilized protein A and protein G
Immobilization of antibodies tagged with oligo dA on magnetic particles with immobilized oligo dT
Immobilization of antibodies on magnetic carriers with immobilized boronic acid derivative via their carbohydrate units on the Fc part

than antibodies bound to magnetic particles. The indirect technique is recommended when the target cell has a low surface antigen density or a cocktail of monoclonal antibodies is used. The direct method is usually faster and requires less antibody than the indirect method. Also, the direct method is advantageous when one does not want to cover all antigen sites with antibody.

Typically, 95–99% viability and purity of the positively isolated cells can be achieved with a typical yield of 60–99%. Depletion efficiency often reaches 99.9% and leaves remaining cells untouched. Sequential depletions are markedly more efficient.

Magnetic particles usually do not have any negative effect on the viability of the attached cells. Many types of magnetic particles are usually compatible with subsequent analytical techniques such as flow cytometry, electron and fluorescence microscopy, polymerase chain reaction (PCR), fluorescence *in situ* hybridization (FISH) or cultivation in appropriate nutrient media. In some cases, however, it is necessary to remove larger immunomagnetic particles from the cells after their isolation. The detachment process can be performed in several ways (Table 3).

Incubation time for cell separation is usually 5–60 min while the binding of primary antibodies to secondary coated magnetic particles usually takes 30 min or less. In positive isolation, the purity of cells generally decreases with time, although the yield increases.

Nonspecific interactions of nontarget cells with hydrophobic magnetic particles can be expected. These

interactions can be partially eliminated using bovine or human serum albumin, casein and nonionic tensides such as Tween 20.

Magnetic Separations using other Labels

Antigens Antigens immobilized on magnetic particles can be used for the isolation of antibody expressing or antigen-specific cells. This approach has been successfully used for selection of antigen-specific hybridoma cells or human antibody-producing cell lines.

Lectins Lectins immobilized on magnetic carriers can interact with saccharide residues on the cell surfaces. A typical example of this approach is the application of immobilized *Ulex europaeus* I lectin which binds to terminal L-fucosyl residues present on the surface of human endothelial cells. Magnetic beads can be released from the isolated cells using a free competing sugar.

Oligosaccharides Oligosaccharides immobilized on magnetic particles can be used for the rapid isolation of specific lectin-expressing cells. Target cells bound to the magnetic particles can be released using a free competing saccharide structure.

Bacteriophage *Salmonella*-specific bacteriophage immobilized to a magnetic solid phase has been used for the separation and concentration of *Salmonella* from food materials.

Table 3 Selected typical procedures for detachment of cells after immunomagnetic separation

Incubation of rosetted cells overnight in cell culture medium with subsequent mechanical forces such as firm pipetting, flushing the suspension 5–10 times through a narrow-tipped pipette
Trypsin, chymotrypsin and pronase have general applicability for proteolytic detachment of isolated cells
Detachment with a polyclonal antibody that reacts with the Fab fragments of primary monoclonal antibodies on magnetic beads. This principle is commercialized by Dynal, Norway (DETACHaBEAD)
Using synthetic peptides which bind specifically to the antigen-binding site of primary antibodies (Baxter Healthcare, Deerfield, IL, USA)
Antibodies immobilized via carbohydrate units on the Fc part to the magnetic particles with immobilized $-B(OH)_3$ groups are dissociated with sorbitol
A complex primary antibody–DNA linker can be split enzymatically using DNase
<i>Cryptosporidium</i> oocysts were successfully released from the immunomagnetic particles by decreasing the pH of the suspension (adding HCl)

Erbium ions, ferritin and magnetoferritin have been used for magnetic labelling of both prokaryotic and eukaryotic cells. Magnetotactic bacteria can be introduced into granulocytes and monocytes by phagocytosis which enables their magnetic separation. Submicron magnetic particles of $\gamma\text{-Fe}_2\text{O}_3$ adhere to the surface of *Saccharomyces cerevisiae*, making the cells magnetic and amenable to magnetic separation.

Magnetotactic bacteria, due to the presence of ferromagnetic material in their cells, can be magnetically separated without any labelling. Erythrocytes can be separated by the high gradient magnetic separation technique after conversion of diamagnetic erythrocytes containing oxyferrohaemoglobin into paramagnetic red blood cells by the oxidation of the iron atoms in the cell haemoglobin to the ferric state (methaemoglobin). Erythrocytes, infected by *Plasmodium*, contain paramagnetic hemozoin, that is a component of malarial pigment. The paramagnetic moment of hemozoin is of sufficient magnitude to enable the separation of malaria-infected (hemozoin-bearing) erythrocytes.

Magnetic Separations in Microbiology, Cell Biology, Medicine and Parasitology

IMS and, in some cases, lectin-magnetic separations are often used in the above-mentioned disciplines. In microbiology they are especially used for the detection of pathogenic microorganisms. IMS enables the time necessary for detection of the target pathogen to be shortened. Target cells are magnetically separated directly from the sample or the pre-enrichment medium. Isolated cells can then be identified by standard, specific microbiological procedures. IMS is not only faster but also usually gives a higher number of positive samples. Also sublethally injured and stressed microbial cells can be very efficiently isolated using IMS. The most important microbial pathogens can be detected using commercially available specific immunomagnetic particles; they are used for the detection of *Salmonella*, *Listeria* and *Escherichia coli* O157. New immunomagnetic particles for the detection of other microbial pathogens are under development.

Removal of cancer cells is one of the most important applications of IMS in the area of cell biology and medicine. The first experiments were performed in the 1970s and since then an enormous number of applications have been described. Cancer cells are usually removed from bone marrow prior to its autologous transplantation and using IMS they are detected in blood. Elimination of graft-versus-host disease (GvHD) in allogenic bone marrow transplan-

tation requires an effective removal of T cells from the bone marrow of the donor. A direct method enabled a 10^3 times depletion of T cells.

Magnetic particles are being increasingly used for isolation of human cell subsets directly from blood and other cell sources. B lymphocytes, endothelial cells, granulocytes, haematopoietic progenitor cells, Langerhans cells, leukocytes, monocytes, natural killer cells, reticulocytes, T lymphocytes, spermatozoa and many others may serve as examples. Cells from other animal and plant species have been successfully separated, too.

Not only whole cells, but also cell organelles can be isolated from crude cellular fractions. Dynal (Oslo, Norway) has developed Dynabeads M-500 Subcellular, which are able to isolate rapidly more than 99% of target organelles.

In the area of parasitology *Cryptosporidium* and *Giardia* are the parasites where IMS is of interest. Two commercially available kits can be used for this purpose. Both products are used in the method 1622: *Cryptosporidium* in Water by Filtration/IMS/FA (December 1997 Draft) of the US Environmental Protection Agency. In very low turbidity samples (clean waters), IMS has demonstrated significantly better results than the standard procedures. When water samples were turbid, the recovery efficiency of IMS diminished.

Future Developments

Magnetic separation of cells is a simple, rapid, specific and relatively inexpensive procedure, which enables the target cells to be isolated directly from crude samples containing a large amount of nontarget cells or cell fragments. Many ready-to-use products are available and the basic equipment for standard work is relatively inexpensive. The separation process can be relatively easily scaled up and thus large amount of cells can be isolated. New processes for detachment of larger magnetic particles from isolated cells enable use of free cells for *in vivo* applications. Modern instrumentation is available on the market, enabling all the process to run automatically. Such devices represent a flexible platform for future applications in cell separation.

IMS play a dominant role at present but other specific affinity ligands such as lectins, carbohydrates or antigens will probably be used more often in the near future. There are also many possibilities to combine the process of cell magnetic separation with other techniques, such as PCR, enabling the elimination of compounds possibly inhibiting DNA polymerase. New applications can be expected, especially in microbiology (isolation and detection of

microbial pathogens) and parasitology (isolation and detection of protozoan parasites). No doubt many new processes and applications in other fields of biosciences and biotechnologies will be developed in the near future.

CELLS AND CELL ORGANELLES: FIELD FLOW FRACTIONATION

P. J. P. Cardot, S. Battu,
T. Chianea and S. Rasouli,
Université de Limoges, Limoges, France

Introduction

Analysis and sorting of living cells and purification of cell organelles are important procedures in the life sciences. There is a wide range of techniques and methodologies available, which can be divided into three main groups. The techniques in the first groups are based on physical criteria such as species size, density and shape, and include centrifugation, elutriation and field flow fractionation. Those in the second group are linked to cell surface characteristics, while flow cytometry techniques make up the third group. At a fundamental level, field flow fractionation (FFF) exploits the physical characteristics of the cells or cell organelles. However, cells or cell organelles exhibit some specific characteristics that can be described by a multipolydispersity matrix. The different physical characteristics of these biological materials require different FFF techniques and modes of operation. Special care must be taken if biological integrity and viability are to be preserved.

Specific Cell Characteristics

Cellular materials range in size from 1 µm to 50 µm. Cell populations are classified by a set of morphological, functional and biophysical characteristics. The biophysical characteristics are of particular interest in FFF. Usually, separations in FFF are influenced (but not directed) by surface properties of the sample components (to avoid particle–particle or particle–separator interactions). These properties can be modulated by the use of appropriate carrier-phase modifiers (surfactants). In terms of FFF separations, mass, size and density appear to be the major first order parameters. However, size is generally defined by the radius or the diameter of a sphere whose volume is identical to that of the cell. Size can therefore be deduced accurately if the cell of interest is perfectly spherical. However, this is not usually the case, and the sphericity index, I , is then used:

$$I = \frac{4.84(V^{2/3})}{S}$$

In this equation V is the cell volume and S is its surface area can be difficult to determine. In terms of cell population, these dimensions are averages and should be associated with a variance. These general

The cleaning procedure involves flushing the channel (ten times the void volume) with a hypo-osmotic carrier phase to destroy the cells, then with a classical deproteinization agent (ten times the void volume) to desorb and destroy the cell and surfactant proteins adsorbed in the FFF separator. Finally the system is flushed again with the hypo-osmotic carrier phase.

Decontamination is performed by allowing a hypochloride solution (3–6°C) to flow through the whole FFF system. The volume used should be three to four times the void volume of the FFF device. Prior to injection the channel should be flushed with ethanol and rinsed with the sterile mobile phase. Decontamination and sterilization can be simultaneous if a 5°C hypochloride solution is used with a 70°C ethanol solution.

Cell Detection, Viability and Recovery

At the outlet of the channel it is necessary to obtain eluted material that retains its integrity, that is the diagnosis of the whole particle. Photometric devices operated in the light scattering mode can be used to follow elution. After fraction collection off-line analyses methods such as microscopy, granulometric or flow cytometry analyses are recommended. Cell specific staining is also possible. Cell viability can be diagnosed by means of specific tests, and recovery must also be clearly defined.

Conclusions

The choice of FFF separation techniques for purification of cell or cell organelle populations is influenced by their possible elution modes. Micron sized species eluted under the steric hyperlayer model can be separated using sedimentation techniques if their density differs from that of the carrier phase medium. This is also possible for 'nonbuoyant' sub-micron sized cell organelle species eluted according to the 'Brownian' elution mode.

If species are to be separated according to their size, FFF techniques that use a flow generated external field are preferred. If differences in surface characteristics are important, electrical-based FFF techniques

should be chosen. For large sample volume preparations, SPLIT techniques are useful, whatever the external field. The major technical goal in cell separation is not the set-up of the separator, but the construction of a chain of knowledge. The separator is designed according to the sample characteristics as well as the mode of operation. Cleaning and sterilization procedures, and detection and viability procedures, are linked to the nature of the material to be purified. This 'biotechnological' process is of major importance for FFF separations in the life sciences.

CHELATING ION EXCHANGE RESINS

R. J. Eldridge, CSIRO Molecular Science,
Clayton South, Victoria, Australia

Copyright © 2000 Academic Press

Introduction

The useful role of ion exchange is to separate a solution at a low initial concentration C_i into a small

volume of concentrate and a much larger volume of depleted solution. In favourable cases the concentration C_e of the target species in the regeneration effluent approaches the regenerant concentration C_r . The concentration factor achieved is then given approximately by:

$$R \equiv C_e/C_i \approx C_r/C_i \quad [1]$$

One usually wants to separate a single valuable species from the other constituents of the initial solution, and the ion exchanger must then be selective for the target species. (Separation can also be achieved by selective desorption, but selective adsorption is preferable because more of the available resin capacity is occupied by the target ion.) The affinity of a resin for a single ion M , under given conditions, can be represented by a distribution coefficient, defined by:

$$D \equiv \frac{\text{amount of } M \text{ on unit mass of resin}}{\text{amount of } M \text{ in unit volume of solution}} \quad [2]$$

Selectivity between two ions can be expressed by a separation factor, defined by:

$$\alpha \equiv C_e^T \cdot C_d^U / C_d^T \cdot C_e^U \quad [3]$$

where C^T represents the concentration of the target and C^U that of an unwanted species, while C_e refers to the regeneration effluent and C_d to the depleted solution.

Common strong acid resins show a small degree of selectivity between singly and doubly charged cations, and even within these categories. Table 1 shows some selectivity values from the literature for a typical strong acid cation exchanger. These are rational equilibrium constants for the reaction:

defined by:

$$K \equiv A_M \cdot a_{\text{Na}}^n / A_{\text{Na}}^n \cdot a_M \quad [5]$$

where A_M is the activity (on the rational scale) of M^{n+} bound to the resin phase and a_M the activity (molal scale) of the salt MX_n in the solution phase. A_{Na} and a_{Na} are the activities of the analogous sodium species. The observed values are too small to allow

one cation from a mixture to be selectively concentrated by a large factor.

Weak acid resins tend to be more selective than strong acid. Table 1 also lists some selectivity coefficients (not constants), defined by:

$$K' = M_M \cdot m_{\text{Na}}^2 / M_{\text{Na}}^2 \cdot m_M \quad [6]$$

for adsorption of divalent cations M^{n+} on a carboxyl resin initially in the Na^+ form. Here M_M is the molal concentration of M^{n+} in the resin phase and m_M its molality in the solution phase. Although K' and K are only roughly comparable, the carboxyl resin is clearly more selective among these four divalent cations.

Chelating Resins

Ion exchangers incorporating chelating groups have higher selectivity among cations than conventional strong or weak acid resins. (In one sense, adsorption of a di- or trivalent cation by any resin is a chelation process, since the ion is coordinated by two or more ligands linked by a chain of covalent bonds, but the term chelating resin is more usually reserved for resins containing discrete chelating groups, each attached to a single monomer unit. A given cation may be coordinated by one or more of these chelating units.) Technical aspects of their use were outlined by Waitz in 1979. A review and a monograph emphasizing analytical applications were published by Warshawsky and Marhol, respectively, in 1982. A comprehensive review by Sahni and Reedijk appeared in 1984, and a shorter update by Beauvais and Alexandratos in 1998.

Resins with an enormous variety of chelating ligands have been synthesized in the laboratory, but few have been manufactured commercially. Essentially any complexing agent used in analytical chemistry can be coupled to a resin, although the challenge to the synthetic chemist is to avoid sacrificing ligand groups such as thiol or primary amino groups in the coupling reaction. Many published syntheses have been too complex to be economic on an industrial scale or have yielded resins of low stability, but new resin structures continue to be reported. In this review we can consider only a few illustrative examples.

Table 1 Selectivities of strong and weak acid cation exchangers^a

Ion	Na^+	K^+	Mg^{2+}	Ca^{2+}	Zn^{2+}	Ni^{2+}	Cu^{2+}	Pb^{2+}

Early chelating resins based on phenolic polymers were largely displaced by styrene-divinylbenzene resins, functionalized via chloromethylation, because of their greater stability. More recently, acrylic polymers have gained ground, with glycidyl methacrylate being a favoured monomer because ligands are easily coupled by reaction with its epoxide group, although possible hydrolysis of the ester link at extremes of pH limits the applicability of these resins. Sherrington, Driessen and their co-workers have used this strategy to prepare a suite of chelating resins containing nitrogen heterocycles. Similarly, Chanda and Rempel have coupled a wide range of chelating groups to polybenzimidazole beads activated with epichlorohydrin.

Table 2 lists some commercially available chelating resins. The order of preference for iminodiacetate resins is typically:

Univalent cations: Ag > Li > Na > K > Rb > Cs
 Divalent cations: Hg > U(VI) > Cu > Pb > Ni
 > Cd ≈ Zn > Co > Fe > Mn
 > Ca > Mg > Ba > Sr
 Trivalent cations: Cr > In > Fe > Ce > Al > La

Structures for the iminodiacetate and aminophosphonate groups are shown in **Figure 1**. Some selectivity coefficients (no definition given) for iminodiacetate resins, recalculated from Waitz, are collected in **Table 3**.

Iminodiacetate Resins: Mercury

Iminodiacetate resins are clearly more selective among the transition metals than are weak acid

**Figure 1** Chelating functionalities: (A) iminodiacetic acid and (B) aminophosphonic acid.

resins. Adsorption of all metal cations decreases with decreasing pH, and uptake of moderately preferred ions such as Ni²⁺ and Zn²⁺ becomes negligible at pH 1–2, but Hg²⁺ and Cu²⁺ are still strongly adsorbed. For Hg²⁺ in sulfuric acid, $D \approx 2 \text{ L g}^{-1}$ at pH 1. The advantage of this high selectivity is illustrated by some results for treatment of a highly acidic, mercury-containing smelter wastewater. Simulated wastewater containing Hg(II), Zn(II), Fe(III), Cd(II) and Pb(II) salts at pH 1.5 was treated with an iminodiacetate resin in bench-scale column runs. **Table 4** and **Figure 2** show the composition of the column effluent over 157 bed volumes. Uptake of Hg(II) was close to 100%, while most of the other cations were not significantly adsorbed. Adsorption of mercury can be represented by:

It appears that a small amount of Pb(II) is adsorbed initially, then displaced by Hg(II). Fe(III) is adsorbed more strongly than Pb(II), but still less strongly than Hg(II). Uptake of iron can essentially be eliminated by reducing Fe(III) to Fe(II), which is not significantly adsorbed at this low pH.

Regeneration with Complexation

Chelating resins are commonly regenerated with mineral acid, but in some cases the resin's affinity for the target metal is too great for this to succeed. In the Hg(II)-iminodiacetate system desorption with nitric acid failed because of the very strong complexation of Hg(II). Concentrated NaCl solution was an effective regenerant because Cl[−] ions convert Hg²⁺ to a series of chlorocomplexes (**Figure 3**). In other words, Hg²⁺ is adsorbed more strongly than H⁺, but can be displaced even by Na⁺ because it is simultaneously complexed by Cl[−]. In this example, both adsorption and desorption steps are selective for Hg(II) over

Table 3 Selectivities at pH 4 of an iminodiacetate chelating resin, relative to Ca²⁺

most elements, although Fe(III) shares the ability of Hg(II) to adsorb as a cation and desorb as a chloro-complex. The regeneration reaction can be written:

Alkaline Earths

The formation of chelate complexes is often regarded as an exclusive property of transition metal cations, but both iminodiacetate and aminophosphonic resins chelate alkaline earth cations and consequently are highly selective for them relative to the alkali metal cations. Separation factors achievable with iminodiacetate resins are reported to be 50–60 for Mg/Na and 500–600 for Ca/Na at pH 7–10;

for aminophosphonate resins $\alpha_{\text{Na}}^{\text{Mg}} \approx 1000$ and $\alpha_{\text{Na}}^{\text{Ca}} \approx 20\,000$. These resins are very effective in softening applications, including, as an extreme case, the removal of low levels of unwanted divalent cations from brine in caustic chlorine plants, despite the great excess of sodium ions.

Amidoxime Resins: Uranium from Seawater

The possibility of recovering valuable metals from the oceans presents a challenge to designers of chelating resins. Uranium is present in seawater at about 14 nmol L^{-1} ($3 \mu\text{g L}^{-1}$), predominantly as the tricarbonyluranate(VI) anion $\text{UO}_2(\text{CO}_3)_3^{4-}$. Recovery by ion exchange would require an extremely selective sorbent, since seawater also contains Na^+ at

Figure 2 Separation of metal cations on an iminodiacetate resin at pH 1.5. Triangles, Pb(II); open diamonds, Cd(II); squares, Zn(II); circles, Fe(III); filled diamonds, Hg(II). (Reproduced with permission from Becker NSC and Eldridge RJ (1993) *Reactive Polymers* 21: 5.)

Figure 3 Regeneration of a chelating resin may require a complexing eluant: desorption of Hg(II) from an iminodiacetate resin with 3 mol L⁻¹ sodium chloride (circles) or 2 mol L⁻¹ nitric acid (squares). (Reproduced with permission from Becker NSC and Eldridge RJ (1993) *Reactive Polymers* 21: 5.)

0.6 mol L⁻¹, Mg²⁺ at 0.4 mol L⁻¹ and transition metal ions such as Fe³⁺, Cu²⁺ and Zn²⁺, at 10–100 nmol L⁻¹. Iminodiacetate resins fail to adsorb significant amounts of uranium from seawater, since their UO₂²⁺/Mg²⁺ selectivity coefficient is only ~ 600. During the 1980s, amidoxime resins derived from polyacrylonitrile (**Figure 4**) were extensively investigated by several research groups, particularly in Europe and Japan, and shown to adsorb up to about 1 mg U g⁻¹ resin from spiked seawater. Distribution coefficients decrease in the order:

from ~ 300 L g⁻¹ for Fe(III) and U(VI) to ~ 20 mL g⁻¹ for Mg(II). UO₂²⁺ cations are believed to be complexed by two deprotonated amidoxime groups, which displace the carbonate ligands. Adsorption rates are higher for resins incorporating hydrophilic cross-linkers or comonomers. Hydrochloric acid at 0.5–1 mol L⁻¹ is an effective regenerant, but causes some hydrolysis of the amidoxime groups.

Figure 4 Synthesis of an amidoxime resin from polyacrylonitrile.

In one experiment with unspiked seawater, an experimental amidoxime resin adsorbed 1 mg g⁻¹ uranium ($D \approx 300$ L g⁻¹). Fe³⁺, Cu²⁺ and Zn²⁺ were concentrated by similar factors. Isolation of pure uranium would therefore need selective regeneration or post-treatment of the regeneration effluent.

Amidoxime resins are also highly selective for Ga(III) at high pH and have been used to recover gallium from Bayer liquor. Again, capacity loss is a problem.

Oligoamine Resins

Many of the transition metal cations are strongly coordinated by uncharged nitrogen-containing ligands. Consequently, chelating resins possessing strongly electron-donating nitrogens will selectively remove Cu²⁺, for example, from solutions containing alkali and alkaline earth cations. Since the resin is uncharged, the adsorbed cations must be accompanied by mobile counterions to maintain electroneutrality. SenGupta has exploited this effect to adsorb anions such as phosphate, selenite, oxalate and phthalate on copper-loaded picolylamine resins (Dow 2N or 3N). These coordinating anions displace anions, such as sulfate, that are associated with adsorbed Cu(II) only by electrostatic attraction. Loss of copper from the resin during ligand exchange is extremely small.

Even conventional weak base resins – usually used as anion exchangers – are capable of separating transition metals from alkaline earths. Uptakes of

Cu(II) have been demonstrated at pH 5 on the phenolic weak base resin Duolite A7 and the acrylic weak base Amberlite IRA35 comparable to their anion exchange capacities ($1\text{--}2\text{ meq g}^{-1}$). Uptake of Ni(II) or Zn(II) was smaller. Regeneration with mineral acid was efficient. An aminophenol resin of similar structure to Duolite A7 was found to adsorb Cu(II), presumably accompanied by sulfate ions, from CuSO_4 solutions at pH 4–7. Other transition metal ions (Fe^{2+} , Co^{2+} , Ni^{2+} , Zn^{2+} , Cd^{2+} and Hg^{2+}) were scarcely adsorbed in this pH range, but in the protonated form (pH ≈ 2) the resin became highly selective for Fe^{3+} .

The transition metal affinity of resins having aliphatic oligoamine substituents increases with chain length (number of amino groups in each chelating group). It has been reported that acrylic oligoamine resins (Figure 5) can adsorb significant amounts of Cu^{2+} , Ni^{2+} , Zn^{2+} or Cd^{2+} from solutions containing ethylenediaminetetraacetic acid (EDTA), provided alkaline earth cations are also present. Transition metal uptakes were highest on resins derived from tetraethylenepentamine or pentaethylenhexamine.

Diphonix

A similar coordination mechanism operates in the adsorption of some metal ions from highly acidic solution on phosphonic acid resins, for example actinide ions on Diphonix[®], one of very few new chelating resins to be introduced commercially in the 1990s. The chelating groups in this resin are contributed by vinylidene-1,1-diphosphonic acid monomer units, but the resin also contains acrylic acid and styrenesulfonic acid units (Figure 6). As with the amidoxime resins described above, hydrophilic monomers are essential for high reaction rates. Diphonix is the outcome of work at the Argonne National Laboratory on 1,1-diphosphonic acid ligands and at the University of Tennessee on ion exchangers possessing two or more types of functional group, operating by different mechanisms. It was developed primarily for actinide separations in highly acidic media, but also strongly adsorbs divalent transition metal cations at pH 1–2 and trivalent cations at pH 0–2.

Figure 5 Acrylic oligoamine resin.

Figure 6 Structure of Diphonix[®].

In pH 1 nitric acid distribution coefficients on Diphonix decrease in the order:

from $\sim 3\text{ L g}^{-1}$ to $\sim 500\text{ mL g}^{-1}$. For these ions a double-logarithmic plot of the distribution coefficient against $[\text{H}^+]$ has slope $-n$, where n is the cation charge. This indicates that adsorption occurs by simple exchange of M^{n+} for H^+ . In 1 mol L^{-1} nitric acid, the order of selectivity is:

with D as high as 900 L g^{-1} for Th(IV) and 200 L g^{-1} for Fe(III) and U(VI), decreasing to 400 mL g^{-1} for Al(III) and 80 mL g^{-1} for Cr(III). Uptake of the strongly preferred ions shows little pH dependence, indicating adsorption without displacement of H^+ on phosphonic acid groups that are not significantly ionized under these conditions. To maintain electroneutrality, the complexed metal ions must be associated with anions from solution, either free or in mixed-ligand complexes containing phosphonic acid groups and small ion ligands such as Cl^- . The less preferred ions show simple ion exchange behaviour over a limited pH range, but uptake increases at high acid concentrations, indicating a change in mechanism.

The very high affinity of Diphonix for Fe(III) makes it very suitable for removing iron from acidic copper electrolytes in copper production by electrowinning. The process has been demonstrated in pilot-scale trials at copper refineries, with no decrease in resin performance over hundreds of cycles. Fe(III) is desorbed by reducing it to Fe(II).

Circumventing Limitations to Selectivity

The selectivity between two cations of a chelating resin should in principle be equal to that of the chelating ligand itself, but this is seldom true in practice. For example, iminodiacetate resins are very much less

Table 5 Comparison of an iminodiacetate resin with the iminodiacetate ion^a

Ion	Ca ²⁺	Fe ²⁺	Co ²⁺	Cd ²⁺	Zn ²⁺	Ni ²⁺	Pb ²⁺	Cu ²⁺	Hg ²⁺
<i>K''</i>	1.00	4.0	6.7	15	17	57	1200	2300	2800
<i>K_m</i>	1.00	1600	2.3 × 10 ⁴	600	2.8 × 10 ⁴	4.7 × 10 ⁵	7 × 10 ⁴	9 × 10 ⁷	1.5 × 10 ⁹

^aSelectivities for divalent cations (relative to Ca²⁺) of an iminodiacetate chelating resin (*K''*) and the iminodiacetate ion (*K_m*).

selective than the free iminodiacetate ion, as shown in Table 5, which compares equilibrium constants for the reaction:

with the corresponding values from Table 3 for iminodiacetate resins. There are several reasons for the discrepancy. In the first place the resin is heterogeneous on a molecular scale. Its chelating groups are located in environments that may vary in polarity, dielectric constant or steric crowding, depending for example on their closeness to cross-links. This variation in chemical environment affects the binding constant for different metal ions to differing extents, degrading the selectivity of the resin. Secondly, the high local concentration of ligands in the resin may lead to a mixture of 1 : 1, 2 : 1 and higher complexes. At loadings less than 100%, the number of ligands coordinated to each metal ion is almost impossible either to control or to measure. Thirdly, the exchange reaction itself changes the properties of the resin. Selectivities of simple ion exchangers are well known to vary with the extent of loading, and the same will be true of chelating resins, especially when adsorbed metal ions are coordinated by ligands attached to different polymer chains, reversibly creating additional cross-links. The result of these factors is not merely reduced selectivity of polymeric resins relative to low molecular weight ligands, but in some cases the order of selectivity is reversed (Table 5).

The mixed composition and additional cross-link effects can be eliminated by designing the resin to accommodate the maximum coordination number of the cation with a single multidentate ligand. Resins containing EDTA moieties are an example. These were synthesized by Takeda *et al.* at Asahi Chemical in 1985, with *m*-divinylbenzene as the essential building block. Addition of bromine across one double bond before polymerization allowed the introduction of an iminodiacetate group on each carbon of the pendant C₂ chains. However, even in these resins, ligands still experience a range of chemical environments.

Oligoamine weak base resins suffer an additional source of heterogeneity since the amine (diethylenetri-

riamine (DETA), for example) can attach to the precursor resin (chloromethylated polystyrene-co-divinylbenzene) through either primary or secondary nitrogens, and can react with multiple chloromethyl groups, introducing additional covalent cross-links. This effect was eliminated in experimental resins: the primary nitrogens of DETA were blocked by forming Schiff base adducts, followed by amination exclusively through the secondary nitrogen and subsequent hydrolysis of the Schiff base groups to recover the primary amino groups (Figure 7). The latter were then converted by further reaction to iminodiacetate, aminophosphonate or other chelating groups. The selectivity sequence of the *bis*(iminodiacetate) derivative is:

with distribution coefficients decreasing from ~ 10 L g⁻¹ at pH 1 for Fe(III) to ~ 10 mL g⁻¹ for Al(III) at pH 2. The resin readily separates Ga(III) and In(III) from Zn(II) and Al(III) in acid solution, but Fe(III) and Cu(II) must first be removed (by precipitation as sulfides, for example). For most trivalent rare earth cations, *D* ≈ 100–500 mL g⁻¹ at pH 2, with the highest values being observed for the medium atomic

Figure 7 Synthesis of diethylenetriamine resin coupled exclusively through the secondary nitrogen, and conversion to a *bis*(iminodiacetic acid) derivative.

Figure 8 Lysine- N^{α},N^{α} -diacetic acid resin.

weight lanthanides (Sm-Dy). The selectivity is great enough to permit chromatographic separation of pairs of lanthanides (La/Pr or Nd/Sm).

The effect of inhomogeneity can be minimized by introducing spacer groups between the chelating groups and the polymer backbone. A highly selective nitrilotriacetate-like resin was synthesized by functionalizing a polystyrene matrix with lysine- N^{α},N^{α} -diacetic acid (**Figure 8**). This resin shows high selectivity for trivalent ions such as Ga(III) and In(III) over divalent cations. When loaded with Fe(III) it can be used to adsorb As(III) and As(V) oxyanions by ligand exchange.

Sulfur Ligands

In the quest for high affinity and high selectivity, many sulfur-containing ligands have been investigated, including thiol, thioether and thiocarbonyl groups, as well as sulfur–nitrogen heterocycles. Thiol resins are available from several manufacturers. Although falling outside the above definition of chelating resins, they can be regarded as the prototype of resins containing thiocarbonyl, thioether or dithiocarboxylate groups, or multiple ligands such as thiol/amino combinations. Thiol resins have been used for adsorption of mercury(II) and are effective in the presence of competing ligands such as Cl^- . However, regeneration is difficult, requiring concentrated acid, and the thiol group is prone to oxidation.

Sulfur-containing ligands tend to have high affinity for platinum group metals (PGM). Isothiuronium resins (**Figure 9**), first prepared in the 1960s by Koster and Schmuckler and subsequently commercialized in both gel (Srafion) and macroporous (Monivex) versions, adsorb PGM from strongly acidic solution and require complexing agents for regeneration. Adsorption is believed to be by simple ion exchange when the functional groups are fully protonated, but this not

achievable in the gel resin, and adsorption then involves both electrostatic and complexing interactions.

Isothiuronium resins have been used in laboratory- and pilot-scale PGM separations from HCl leach solutions, with thiourea or thiocyanate as regenerant. However, new sulfur–nitrogen resins are still being reported for heavy metal and PGM applications. Polybenzimidazole functionalized with dithiooxamide was found to be strongly selective for Pd(II) and Pt(IV) over first-row transition metals in acidic solution. Other researchers report similar behaviour with resins containing, for example, thiosemicarbazide, dithizone, thiadiazole or thiotetrazolium substituents.

Kinetics

Adsorption and desorption rates are an important consideration in ion exchange, as well as equilibrium behaviour. Complexation rates benefit from small particle size, high porosity and, as noted above, high hydrophilicity. Capturing the rate advantage of small size requires a solution to the problem of handling fine particles. Incorporating a magnetic component is one strategy that has been demonstrated. Resins can also be made in nonconventional formats, such as graft copolymers or fine fibres, to keep diffusion paths short. A range of fibrous sorbents was developed under the name Fiban, derived from polyacrylonitrile fibres or polypropylene fibres grafted with styrene, including a chelating material containing imidazoline groups derived from polyacrylonitrile. These sorbents could be used to form filaments or nonwoven fabrics. Similarly, others have reported amidoxime sorbents made from polyacrylonitrile fibre and woven into cloth for use in uranium recovery, and polyacrylonitrile-g-glycidyl methacrylate fibres (Tiopan) functionalized with ligands including thiosemicarbazide, 8-mercaptoquinoline and 2-aminothiazole.

Conclusion

Ingenious syntheses of chelating resins continue to be reported. However, large scale applications for such materials are limited, and few are likely to be produced

Figure 9 Isothiuronium group.

industrially. The main markets appear to be in the production of low volume, high value elements: precious metals, rare earths with valuable optical properties and raw materials for electronic devices. Applications in lower value fields such as waste management or by-product recovery should benefit from novel resin formats designed for improved resin/liquid contacting.

CHEMICAL WARFARE AGENTS: CHROMATOGRAPHY

P. A. D'Agostino, Medicine Hat, Alberta, Canada

Copyright © 2000 Academic Press

Introduction

The development and application of analytical methods for the analysis of chemical warfare agents have received increased attention, due in large part to the recently ratified Convention on the Prohibition of the Development, Production, Stockpiling and Use of Chemical Weapons and their Destruction (commonly referred to as the Chemical Weapons Convention or CWC). After considerable effort the CWC was opened to signature in 1993, with the treaty coming into force on 29 April 1997. The treaty has been ratified by 120 states, all of which agree not to develop, produce, stockpile, transfer or use chemical weapons and agree to destroy their own chemical weapons and production facilities. A strong compli-

ance-monitoring regime involving site inspections was built into the CWC to ensure that the treaty remains verifiable. The Organisation for the Prohibition of Chemical Weapons, or OPCW, based in The Hague, has responsibility for implementation of the treaty. Routine OPCW inspections have or will take place at declared sites, including small scale production, storage and destruction sites, and challenge inspections will take place at sites suspected of non-compliance.

An analytical capability will be required to help verify compliance with the treaty, since inspectors will have the option to take and analyse suspect samples to help establish compliance or noncompliance. Gas chromatography is the current method of choice for the separation and analysis of chemical warfare agents, with this technique being employed in the field-portable gas chromatographic-mass spectrometric (GC-MS) instrumentation in use by the OPCW inspectorate.

Chemical warfare agents are a group of toxic chemicals that have been defined in the CWC as 'any chemical which through its chemical effect on life processes can cause death, temporary incapacitation or permanent harm to humans or animals...'. Poisonous or toxic compounds have been utilized in an effort to gain military superiority throughout history but it is only during the past century that chemical warfare agents have been produced and used on a large scale. Tear gas grenades were used in 1914 by the French at the outbreak of World War I, but it was not until the Germans first used chlorine near Ypres in 1915 that the world entered the modern era of chemical warfare. Other chemical warfare agents such as phosgene and mustard were used by both sides in World War I.

The use and development of chemical warfare agents continued after World War I despite the signing of the 1925 Geneva Protocol, which bans the first use of chemical weapons. Mustard was used by the Italians against the Abyssinians (Ethiopia) during 1936–1937, and just prior to World War II, the Germans discovered and produced the first nerve agent, tabun. Nerve agents were made into weapons by the Germans but neither side made use of their chemical weapons stock. More effective nerve agents, such as VX, were developed in the 1950s, mustard was used in the Yemen War (1963–1967), and allegations of chemical warfare agent use were reported in South-East Asian conflicts. Nerve and mustard agents were used by Iraq in the 1980s war between Iran and Iraq, and were considered a real threat to United Nations armed forces during their action against Iraq (1990–1991). More recently, sarin was used against the population of a Kurdish village in 1993 and again in 1995 by terrorists in the Tokyo underground transit system. Proliferation of chemical weapons and their use will hopefully decrease over the coming years as the CWC proceeds towards its goal of worldwide chemical weapons destruction.

Chemical Warfare Agent Categories

Chemical warfare agents have been classified into nerve, blister, choking, vomiting, blood, tear and incapacitating agent categories based on their effect on humans. The most significant chemical warfare agents in terms of military capacity and past use are the nerve and blister agents. For these reasons the analysis of these compounds will be emphasized over the other groups. The choking, blood and vomiting agents are for the most part obsolete chemical agents that were employed during World War I. The tear agents were used during the Vietnam War but their primary use, because of their inability to produce

high casualties, remains in riot control and for the training of military personnel in chemical defence. Incapacitating agents have been included as the USA did develop an agent in this category.

The compounds listed in Table 1 represent the most common chemical warfare agents, grouped by category with their Chemical Abstracts registry numbers, and is not intended to be exhaustive. It has been estimated that more than 7000 compounds are controlled under the CWC, although in practical terms the actual number of chemical warfare agents, precursors, degradation products and related compounds that are contained in the OPCW GC-MS database is in the hundreds. The structures of some common nerve and blister chemical warfare agents are illustrated in Figure 1.

Gas Chromatographic Methods

Chemical warfare agents have often been referred to as warfare gases and, in the military, the phrase 'gas, gas, gas' has become synonymous with attack by chemical warfare agents. In fact, many chemical warfare agents exist as liquids at ambient temperatures but have varying degrees of volatility and pose a significant vapour hazard as well as a liquid contact hazard. This physical characteristic has made the analysis of chemical warfare agents amenable to gas chromatography (GC) with a variety of detectors including mass spectrometry (MS).

The OPCW, an important end-user of analytical techniques for chemical warfare agents, requires the use of two or more spectrometric techniques and the availability of authentic reference standards for the unambiguous identification of these controlled compounds. For this reason, the combined use of GC–Fourier transform infrared spectrometry (FTIR) has received increased attention as newer technologies have led to detection limits approaching those routinely reported during GC-MS analysis. For analyses involving low levels of chemical warfare agents in the presence of high levels of interfering chemical background, tandem mass spectrometry (MS-MS) is receiving increased attention.

GC Retention Behaviour

Packed column GC was routinely employed in the past for the analysis of chemical warfare agents, but with the advent of fused silica capillaries this technology has been used less frequently. Capillary column GC has become the most frequently employed analytical separation method for the screening of samples contaminated with chemical warfare agents. Separation of chemical warfare agents may be achieved with fused silica columns coated with poly-

Table 1 Common chemical warfare agents

Full name (trivial name(s))	Chemical Abstracts no.
(a) <i>Nerve</i> (reacts irreversibly with cholinesterase; this results in acetylcholine accumulation, continual stimulation of the body's nervous system and eventual death)	
<i>O</i> -Isopropyl methylphosphonofluoridate (sarin, GB)	107-44-8
<i>O</i> -Pinacolyl methylphosphonofluoridate (soman, GD)	96-64-0
<i>O</i> -Cyclohexyl methylphosphonofluoridate (GF)	329-99-7
<i>O</i> -Ethyl <i>N,N</i> -dimethylphosphoramidocyanidate (tabun, GA)	77-81-6
<i>O</i> -Ethyl <i>S</i> -2-diisopropylaminoethyl methylphosphonothiolate (VX)	50782-69-9
(b) <i>Blister</i> (affects the lungs, eyes and produces skin blistering)	
Bis(2-chloroethyl)sulfide (mustard, H)	505-60-2
Bis(2-chloroethylthio)ethane (sesquimustard, Q)	3563-36-8
Bis(2-chloroethylthioethyl)ether (T)	63918-89-8
Tris(2-chloroethyl)amine (HN-3)	555-77-1
2-Chlorovinyl dichloroarsine (lewisite, L)	541-25-3
(c) <i>Choking</i> (affects respiratory tract and lungs)	
Chlorine	7782-50-5
Carbonyl dichloride (phosgene, CG)	75-44-5
(d) <i>Vomiting</i> (causes acute pain, nausea and vomiting in victims)	
Diphenylarsinous chloride (DA)	712-48-1
10-Chloro-5,10-dihydrophenarsazine (adamsite, DM)	578-94-9
Diphenylarsinous cyanide (DC)	23525-22-6
(e) <i>Blood</i> (prevents transfer of oxygen to the body's tissues)	
Hydrogen cyanide (HCN, AC)	74-90-8
(F) <i>Tear</i> (Causes tearing and irritation of the skin)	
[(2-chlorophenyl)methylene]propanedinitrile (CS)	2698-41-1
2-Chloro-1-phenylethanone (CN)	532-27-4
Dibenz[b,f][1,4]oxazepin (CR)	257-07-8
(g) <i>Incapacitating</i> (prevents normal activity by producing mental or physiological effects)	
3-Quinuclidinyl benzilate (BZ)	6581-06-2

Nerve agents**Blister agents****Figure 1** Structures of common chemical warfare agents.

siloxane or other films and retention index data relative to *n*-alkanes and *n*-alkylbis(trifluoromethyl)phosphine sulfides (M-series) have been reported for many chemical warfare agents and related compounds under temperature programming conditions. Retention indices relative to *n*-alkanes have been reported for 100% dimethyl-polysiloxane (e.g. J&W DB-1), (95%)-methyl-(5%)-diphenyl-polysiloxane (e.g. J&W DB-5), (86%)-dimethyl-(14%)-cyanopropylphenyl-polysiloxane (e.g. J&W DB-1701) and other films. In general, the best separations have been achieved with a moderately polar film such as (86%)-dimethyl-(14%)-cyanopropylphenyl-polysiloxane. **Table 2** lists typical retention index data for several common chemical warfare agents on three different liquid phases under temperature programming conditions.

The use of retention indices relative to *n*-alkanes by the OPCW during on-site inspections is anticipated in the near future to differentiate between controlled compounds that exhibit similar electron impact mass spectrometric (EI-MS) data during GC-MS analysis,

Table 2 GC retention index data for common chemical warfare agents (relative to *n*-alkanes)

Compound name	GC retention index ^a		
	DB-1	DB-5	DB-1701
<i>O</i> -Isopropyl methylphosphonofluoridate (sarin, GB)	792	824	966
<i>O</i> -Pinacolyl methylphosphonofluoridate (soman, GD) ^b	1008	1045	1188
	1013	1049	1193

<i>O</i> -Ethyl <i>S</i> -2-diisopropylaminoethyl methylphosphonothiolate (VX)	1664	1710	1881
Bis(2-chloroethyl)sulfide (mustard, H)	1124	1173	1326
Bis(2-chloroethylthio)ethane (sesquimustard, Q)	1623	1689	1923
Bis(2-chloroethylthioethyl)ether (T)	1910	1983	2241

^aGC retention indices determined with three J&W 0.25 μ m films with the following temperature program: 50°C (2 min), then 10°C min⁻¹ to 300°C (5 min).

^bRetention data for both enantiomer pairs.

but different GC retention behaviour. Application of GC retention indices during the analysis of VX-contaminated samples is likely since the EI-MS data for VX and a number of VX-related compounds are remarkably similar. The EI data for these compounds lack a molecular ion and contain a base ion at m/z 114 due to $(\text{CH}_2\text{N}(\text{iPr})_2)^+$ and additional ions related to the $-\text{SC}_2\text{H}_4\text{N}(\text{iPr})_2$ substituent.

Chiral stationary phases have been developed for the resolution of stereoisomers of several chiral nerve agents, most notably soman. The use of multiple columns of differing polarity during one analysis has also been successfully employed during chemical warfare agent analysis and the term 'retention spectrometry' was coined to describe this technique.

Conventional GC Detectors

Most of the GC detectors commonly applied to pesticide residue analysis have also been applied to the screening of samples for chemical warfare agents. Detection limits are typically in the nanogram to picogram range. Flame ionization detection (FID) is routinely used for preliminary analyses, as this technique provides a good indication of the complexity of a sample extract. **Figure 2** illustrates GC-FID chromatograms obtained using a J&W DB-1 capillary column for three different munitions grade mustard formulations, HT, HS and HQ. HT is typically 60% distilled mustard (H) and 40% bis(2-chloroethyl-

thioethyl)ether (T) by weight, while HQ is usually 75% distilled mustard and 25% sesquimustard (Q) by weight. HS is crude mustard-containing 15% carbon tetrachloride. Munitions grade samples typically contain additional sample components that may provide synthetic procedure or source information. These samples contained several other sulfur-containing impurities, including 1,4-thioxane, 1,4-dithiane (two common mustard degradation products) and several longer chain blister agents (chromatographic peaks 8, 9 and 10 in **Figure 2**).

Figure 3 illustrates the application of capillary GC-FID for the characterization of tabun and related impurities in a munitions grade sample used for military chemical agent detector evaluation. The volatile organic content of this munitions grade tabun was estimated on the basis of the FID response of the individual components. Tabun accounted for 81% of the sample. The impurities, isopropyl *N,N*-dimethylphosphoramidocyanidate (isopropyl analogue of tabun), ethyl *N,N,N',N'*-tetramethylphosphorodiamidate, *N,N,N',N'*-tetramethylphosphorodiamidic cyanide and the cluster of pyrophosphates, represented approximately 5%, 4%, 2% and 5%.

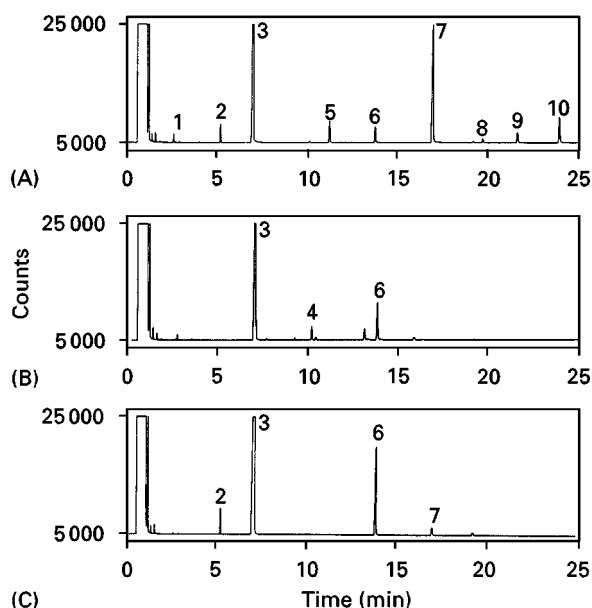

Figure 2 Capillary column GC-FID chromatograms of three munitions grade mustard samples: (A) HT, (B) HS and (C) HQ. Identified compounds include: 1, 1,4-thioxane; 2, 1,4-dithiane; 3, mustard (H); 4, bis(2-chloroethyl)disulfide; 5, 2-chloroethyl (2-chloroethoxy)ethyl sulfide; 6, sesquimustard (Q); 7, bis (2-chloroethylthioethyl)ether (T); 8, 1,14-dichloro-3,9-dithia-6,12-dioxatetradecane; 9, 1,14-dichloro-3,6,12-trithia-9-oxatetradecane; and 10, 1,16-dichloro-3,9,15-trithia-6,12-dioxahaptadecane. (GC column: 15 m \times 0.32 mm ID J&W DB-1, temperature programme: 50°C (2 min), then 10°C min⁻¹ to 280°C (5 min), 2×10^{-10} A full scale.)

Figure 3 Capillary column GC-FID chromatogram of munitions grade tabun (GA) sample. Compounds identified include: 1, tabun (GA); 2, ethyl isopropyl *N,N*-dimethylphosphoramidocyanidate; 3, ethyl *N,N,N',N'*-tetramethylphosphorodiamidate; 4, *N,N,N',N'*-tetramethylphosphorodiamidiccyanide; and 5, pyrophosphates. (GC-column: 15 m \times 0.32 mm ID J&W DB-5, temperature programme: 50°C (2 min), then 10°C min⁻¹ to 280°C (5 min), 5×10^{-11} A full scale.)

The need for higher specificity and sensitivity has led to the application of element-specific detectors such as flame photometric detection (FPD), thermionic detection (TID), atomic emission detection (AED) and electron capture detection (ECD). The simultaneous use of FID with one or more element-specific detectors has also been demonstrated during dual or tri-channel GC analysis using conventional and thermal desorption sample introduction. While these detectors may provide strong collaborative evidence for the presence of chemical warfare agents, they cannot be used for full confirmation. Use of GC with one or more spectrometric technique such as MS is required to confirm the presence of chemical warfare agents.

Mass Spectrometry

Mass spectrometry is the method of choice for the detection and characterization of chemical warfare agents, their precursors, degradation products and related compounds. Extensive use has been made of GC-MS and the mass spectra of numerous chemical warfare agents and related compounds have been published, with the most common chemical warfare agent mass spectra being available in the OPCW, commercial or defence community databases.

Samples collected for chemical warfare agent analysis typically fall into one of the following general categories: (a) munitions or munition fragments (e.g. neat liquid or artillery shell casing); (b) environmental (e.g. soil, water, vegetation or air samples); (c) artificial materials (e.g. paint or rubber); and (d) biological media (e.g. blood or urine). The ease of analysis

depends on the amount of preparation required to obtain a suitable sample or extract for GC analysis. In the simplest case where neat liquid can be obtained the sample requires dilution with a suitable solvent prior to GC-MS analysis. Environmental and other samples generally require (at a minimum) solvent extraction and concentration prior to analysis, with an exception being direct thermal desorption analysis of samples using a GC equipped with a thermal desorption device that may be loaded with the actual sample. Recommended methods for sample preparation have been published by The Ministry of Foreign Affairs of Finland as part of their contribution to Chemical Disarmament.

Figure 4 illustrates the capillary column GC-MS chromatogram obtained for the extract of a soil sample containing VX and several related compounds. Seven components were identified in the sample following ultrasonic extraction of 1 g of soil with dichloromethane. Extraction of chemical warfare agents from biological samples is generally more difficult. Bonierbale, Debordes and Coppet recently demonstrated a method for the extraction of VX from rat blood as part of a study designed to follow the hydrolysis of VX. Figure 5 illustrates a typical mass chromatogram for the blood extract containing VX, malathion and diisopropylaminoethanethiol.

The data acquired in Figures 4 and 5 and most MS data obtained by OPCW inspectors during inspections have been obtained under EI-MS conditions. However, many of the chemical warfare agents in particular the organophosphorus nerve agents such as VX, and the longer chain blister agents related to

Figure 4 Capillary column GC-MS (EI) chromatogram of dichloromethane extract of soil sample contaminated with VX. VX and six other compounds were identified: 1, diethyl methylphosphonate; 2, *N,N*-diisopropylethylamine; 3, 2-(diisopropylamino)ethyl methyl sulfide; 4, *O,S*-ethyl methyl methylphosphonothiolate; 5, *O,S*-diethyl methylphosphonothiolate; 6, VX; and 7, bis[2-(diisopropylamino)ethyl] disulfide. (GC column: 15 m \times 0.32 mm ID J&W DB-1701, temperature programme: 50°C (2 min) then 10°C min⁻¹ to 280°C (5 min).)

mustard, such as Q and T, do not provide molecular ion information during EI-MS. This hinders confirmation of these compounds and makes identification of novel chemical warfare agents or related impurities difficult.

Considerable effort has been devoted to the use of chemical ionization (CI) as a complementary ionization technique. This milder form of ionization generally affords molecular ion information for the chemical warfare agents and has been used extensively for the identification of related compounds or impurities in chemical warfare agent munitions samples and environmental sample extracts. The identity of these related compounds is important because the origin of samples, synthetic process information or degree of degradation (weathering) may be deduced based on this 'fingerprint' data.

Isobutane, ethylene and methane gases were initially demonstrated as suitable CI gases for the acquisition of organophosphorus nerve agent CI-MS data. More recently, the efficacy of ammonia CI-MS for organophosphorus nerve agents and related compounds has been demonstrated and many laboratories now employ this complementary confirmation technique. Ammonia CI not only offers abundant

molecular ion data, but also affords a high degree of specificity as less basic sample components are not ionized by the ammonium ion.

Capillary column GC-MS-MS offers the analyst the potential for highly specific, sensitive detection of chemical warfare agents as this technique significantly reduces the chemical noise associated with complex sample extracts. The specificity of product scanning with moderate sector resolution, as well as the specificity of ammonia CI, were demonstrated with a hybrid tandem mass spectrometer during analysis of painted panel samples circulated during an international round robin verification exercise.

The painted panel extract was contaminated with numerous hydrocarbons. Only two of the three longer chain blister agents, sesquimustard (Q) and bis(2-chloroethylthioethyl)ether (T), could be identified during capillary column GC-MS (EI) analysis (Figure 6A). The arrow indicates the chromatographic retention time of the third blister agent, 2-chloroethyl (2-chloroethoxy)ethyl sulfide (O). The specificity of ammonia CI (Figure 6B) was clearly demonstrated during this analysis. All three longer chain blister agents were determined in the presence of high levels

Figure 5 Capillary column GC-MS (EI) chromatogram of 374 $\mu\text{mol L}^{-1}$ VX incubated for 2 h in the presence of rat plasma. Extracted sample components: 1, 3 $\mu\text{mol L}^{-1}$ malathion; 2, VX; and 3, diisopropylaminoethanethiol. (GC column: 25 m \times 0.32 mm ID CP 8CB; temperature programme: 100°C (0.5 min), then 30°C min⁻¹ to 210°C (1 min) followed by 30°C min⁻¹ to 300°C (3 min).)

Figure 6 Capillary column (A) GC-MS (EI), (B) GC-MS (ammonia CI) and (C) GC-MS/MS (EI) chromatograms obtained during analysis of international round robin painted panel extracts. Sequimustard (Q) and bis(2-chloroethyl (2-chloroethoxy)ethyl sulfide) (T) were detected during EI analysis. The downward arrow in (A) indicates the retention time of 2-chloroethyl (2-chloroethoxy)ethyl sulfide (O). This compound (O) was masked by the organic content of the sample during EI analysis and only detected following (B) ammonia CI and (C) MS-MS analysis. (GC column: 15 m \times 0.32 mm ID J&W DB-1701, temperature programme: 40°C (2 min), then 10°C min⁻¹ to 280°C (5 min).)

of interfering hydrocarbons, as the hydrocarbons were not sufficiently basic to ionize. Similarly, it was possible to use the resolution of hybrid tandem mass spectrometry to discriminate between ions at m/z 123 arising from the longer chain blister agents from those ions at m/z 123 arising from the hydrocarbon background. The resultant GC-MS-MS chromatogram (Figure 6C), where only m/z 123 ions due to the blister agents were transmitted into the collisional activated dissociation cell, was virtually free of chemical noise and all three components were detected.

The three longer chain blister agents were well resolved with the J&W DB-1701 capillary column, with all three components exhibiting similar product spectra during GC-MS-MS analysis.

Hydrolysis Products of Chemical Warfare Agents

Both the nerve and blister agents undergo hydrolysis in the environment and methods are required for retrospective detection and confirmation of these hydrolysis products. Hydrolysis products are significant as they are generally compounds that would not be

routinely detected in environmental samples and their presence strongly suggests the prior presence of chemical warfare agents. The degradation products of the chemical warfare agents, in particular the nerve agents, are nonvolatile hydrolysis products that must be derivatized prior to GC analysis. A variety of derivatization techniques including methylation, *t*-butyldimethylsilylation and trimethylsilylation have been investigated to allow GC analysis of, in particular, the organophosphorus acids related to the nerve agents (e.g. alkyl methylphosphonic acids and methylphosphonic acid).

Mustard and longer chain blister agents hydrolyse to their corresponding diols, with thiodiglycol being the product formed following hydrolysis of mustard. These compounds may be analysed by GC-MS directly provided the sample is loaded onto the column using 'cool' on-column injection. Figure 7 illustrates a typical GC-MS(EI) chromatogram obtained for products formed following hydrolysis of a sample containing both HT and HQ. The principal hydrolysis products of H, Q and T – thiodiglycol, bis(2-hydroxyethylthio)ethane, and bis[(2-hydroxyethylthio)ethyl] ether, respectively – are well resolved with the J&W DB-1701 capillary column. Molecular ion

information for the longer chain hydrolysis products, were obtained under ammonia CI conditions.

Use of thermospray mass spectrometry and, more recently, the use of atmospheric pressure ionization techniques (e.g. electrospray (ESI), ionspray and atmospheric pressure CI), has enabled the direct mass spectrometric analysis of the hydrolysis products of chemical warfare agents. Both techniques may be interfaced to liquid chromatography for component separation, with thermospray having been largely superseded by atmospheric pressure ionization (API) for most LC-MS applications. Examples of LC-ESI-MS methods for the direct analysis of chemical warfare agent hydrolysis products are relatively few, and only recently has this technique been demonstrated for the analysis of the nerve agents as well. These new LC-ESI-MS methods complement existing GC-MS methods for the analysis of chemical warfare agents and their hydrolysis products and will likely replace some GC-MS methods currently in use for the analysis of contaminated aqueous samples.

Safety and Disposal

Chemical warfare agents are extremely hazardous and lethal compounds. They can only be used in designated laboratories by personnel trained in safe-handling and decontamination procedures and with immediate access to medical support. Safety and standard operating procedures must be developed and approved before any chemical warfare agents are handled. Chemical warfare agents can only be used in laboratory chemical hoods with a minimum face velocity of 100 linear feet per minute equipped with emission control devices that limit exhaust concentration to below 0.0001 mg m^{-3} . Personnel handling chemical warfare agents should wear rubber gloves, lab coats and full faceshields, and a respirator (gas mask) must be kept within easy reach. Sufficient decontaminants to destroy all chemical warfare agent being handled must be on hand before commencing operations.

Blister agents such as mustard can be destroyed with 10% hypochlorite or strong bleach solutions. The nerve agents can be destroyed using saturated methanolic solutions of sodium or potassium hydroxide. Decontaminated chemical warfare agents must be disposed of in an environmentally approved method according to local legislation.

Conclusion

Capillary column GC is the chromatographic method of choice for the separation and analysis of chemical warfare agents. This technology is employed in the

Figure 7 Capillary column GC-MS(EI) chromatogram of the hydrolysis products of a munitions grade mustard sample containing HT and HQ. Eight compounds were identified: 1, 1,4-dithiane; 2, mustard (H); 3, hemisulfur mustard; 4, thiodiglycol (hydrolysis product of H); 5, 2-chloroethyl (2-hydroxyethylthio)ethyl ether; 6, 2-chloroethyl (2-hydroxyethylthio)ethyl sulfide; 7, bis(2-hydroxyethylthio)ethane (hydrolysis product of Q); and 8, bis[(2-hydroxyethylthio)ethyl] ether (hydrolysis product of T). (GC column: $15 \text{ m} \times 0.32 \text{ mm ID}$ J&W DB-1701, temperature programme: 40°C (2 min), then $10^\circ\text{C min}^{-1}$ to 280°C (5 min).)

field-portable GC-MS instrumentation currently in use by the OPCW inspectorate. Use of GC with one or more spectrometric technique such as mass spectrometry is required to confirm the presence of chemical warfare agents. For this reason many analyses are carried out by GC-MS under electron impact or chemical ionization conditions. For analyses involving low levels of chemical warfare agents in the presence of high levels of interfering chemical background, GC-MS-MS is receiving increased attention.

Atmospheric pressure ionization (e.g. electrospray (ESI), ionspray and atmospheric pressure CI) techniques may be used for the direct mass spectrometric analysis of the hydrolysis products of chemical warfare agents in aqueous samples. Examples of LC-ESI-MS methods for these analyses are relatively few, and only recently has this technique been demonstrated for the analysis of the nerve agents as well. These new LC-ESI-MS methods complement existing GC-MS methods for the analysis of chemical warfare agents and their hydrolysis products and will likely replace some GC-MS methods currently in use for the analysis of contaminated aqueous samples.

Background

Since its commercial inception in 1988 capillary electrophoresis (CE) has increasingly offered the separ-

ation scientist a very wide range of application (biopolymers to cations), with ultra-high efficiency. It is generally cost-effective, easy in use, with low sample and buffer requirements and has the capability for automation. For these reasons CE has expanded considerably and is now used as an orthogonal and complementary technique alongside well-established analytical procedures. Of all its

application fields, the separation of compounds with one or more chiral centres has been particularly successful. Analytical chiral separations increased in importance throughout the 1980s: considerable interest was generated in the resolution of stereoisomers of food additives, agrochemicals, petrochemicals and pharmaceuticals. During this time the analyst was presented with numerous procedures to examine chiral compounds. Chromatography and, particularly, high performance liquid chromatography (HPLC) with immobilized chiral stationary phases used as column packings was the most successful for separation of enantiomeric mixtures, albeit at considerable cost.

However, chiral separations by chromatography do not give a unique solution to all difficulties relating to the resolution of chiral compounds. Thus, with CE analysts have another tool at their disposal, with all the benefits of the technique to be exploited. Two major processes of separation are undertaken in enantiomeric separations. The commonest procedure is where the enantiomers are resolved directly as diastereoisomers in the conditions of a chiral environment present in the capillary. The transient diastereoisomers are formed *in situ* and resolved on the basis of their different physicochemical properties. Alternatively, conventional CE separations follow after off-line diastereomeric derivatives are produced through reaction of the analyte with optically active reagents, in a procedure which is commonly referred to as an indirect method. An example is the resolution of the diastereomeric pairs of D, L-tryptophan with (+)-diacetyl-L-tartaric anhydride which are resolved on a polyacrylamide-coated, conventional silica capillary. Certain precautions are necessary within this procedure; primarily, a reagent of very high optical purity (100%) is required for specific reaction with the individual enantiomers. Variability in purity of a reagent sample would result in diastereomeric interference and errors in the determination of the analytes. Incomplete reaction and differences in the speed of reaction are also problems which must be addressed when carrying out the derivatization.

Over the last 10 years, a number of CE modes have been examined for separation of stereoisomers. Of these, capillary zone electrophoresis (CZE) in conjunction with chiral additives in the buffer phase is the most frequently used for charged chiral compounds. For neutral chiral analytes (and charged compounds), micellar electrokinetic chromatography (MEKC) has been applied through a chiral surfactant or a chiral additive and achiral surfactant, as additives to the buffer in a conventional silica capillary, when operated at the critical micelle concentration. In contrast to these applications where the selector

acts in free solution, some success with constraining the chiral selector within the capillary has been achieved. Two approaches have been considered – attaching the selector to the capillary wall or trapping it within a gel (in capillary gel electrophoresis), although in practice, limited applications have been reported so far. The most recent proposal for optical separations is through electrochromatography, where a chiral stationary phase is packed into the silica capillary and the mobile phase moves under electroosmotic flow (EOF).

Chiral Selector in the Buffer Phase

Ligand Exchange

CE enantiomeric resolution was first established, through a procedure named ligand exchange. This is based on metal chelate complexation with copper or zinc at the centre of the complex. It was directed towards amino acids, which as dansyl-labelled derivatives were resolved through initially interacting copper (Cu(II)) and L-histidine in the run buffer and then forming a ternary metal complex with an enantiomer of a chiral amino acid. In an enantiomeric mixture the metal complexes can have differential stability, and therefore mobility differences between the enantiomers result. In the case above, a neutral pH buffer was used, which gives a positively charged metal-histidine interaction and the enantiomer forming the higher stability complex migrates faster. One drawback of this procedure is the requirement that the amino acid in the metal-amino acid interaction has to be of very high purity to stop enantiomeric impurities being introduced into the assay. Following the initial research, the same group impressively resolved 14 racemic amino acids by this procedure where the complex was Cu(II)-aspartame. At present the procedure is limited to amino acids, with some extension to peptides and additional separations, and most applications appeared in the early years of CE.

Cyclodextrins

The interest in cyclodextrins (CDs) in the chemical, cosmetic, food and drug industries has grown considerably. In the pharmaceutical field incorporation within the CD has led to improvements in bioavailability, pharmacokinetics and stability. However, to the analyst, their major influence has been in enantiomer stereoselectivity, which originates from the chirality of the glucose units and involves stereochemical interaction through hydrophobic inclusion, hydrogen bonding and often steric repulsion, when the CD is used as an additive in an aqueous CE buffer. The CDs, produced enzymatically from starch, are

comprised of 6–8 D-(+)-glycopyranose units as α -, β - and γ -CD. The molecules are shaped as truncated cones, with relatively hydrophilic exteriors, due to secondary C2 and C3 hydroxy groups at the top and primary C6 hydroxy groups at the bottom of the cone. The rigid structure presents an internal hydrophobic cavity, which will accommodate ring-structured enantiomers. Therefore, for chiral recognition of enantiomers, the most favourable chemical structure is where the hydrophobic centre, such as a cycloalkane or aromatic group (which generally interacts most closely with β -CD), gives a close cavity fit. But one of the enantiomers gives a poorer steric fit, which results in differential binding constants between the enantiomers. Typically, a small molecule with a single aromatic ring will include with a tight fit into the β -CD cavity. Additionally, hydrogen-bonding sites are required for interaction with the secondary hydroxyls on the rim of the cavity and at least one repulsive interaction with the CD. Generally, for interaction with the CDs the chiral molecule's hydrophobic centre should be close to the chiral centre (Figure 1).

CDs are generally reasonably straightforward to work with in CE. They are commercially available, ultraviolet transparent and, during method development, the concentration and the buffer conditions, such as pH, can easily be changed, without the need for long equilibration times. One area of slight difficulty is solubility which, although adequate in water or organic solvent for α and γ (14.5 and 23.2 g per 100 mL in water), is only 1.85 g per 100 mL with the commonly used β -CD. Other general properties are

that CDs are neutral molecules and that the difference in electrophoretic mobility in mixtures has to occur from the charge on the chiral analytes. In method development it is important to optimize the enantiomeric separation, and there are three main areas of interest, two of which revolve around solvation effects, influenced through varying the pH and the organic additive concentrations. The CD concentration is also important: a theoretical model, has been described which indicates a maximum concentration for enantiomeric resolution. Other researchers have confirmed this and extended discussions to chiral separation models which include the function of pH and organic additives in the buffer. Other parameters shown to have an influence on resolution include buffer concentration and internal diameter of the capillary.

It was clear, however, in method development and in stereoselective HPLC assays with chiral additives that the solubility of the native CDs was a limiting factor, particularly with β -CD. As a result a large number of CD derivatives have been synthesized and tested and are now commercially available for use in CE. These range from the electrophoretically neutral methylated β -CD and hydroxypropyl β -CD to charged species, such as methylamino β -CD and sulfobutylated β -CD. In the former case solubility is improved manifold and, in the latter case, in addition to improved solubility the charge on the CD gives electrophoretic mobility to uncharged and neutral chiral compounds. Apart from these advantages the derivatized CDs often have different enantioselectivities over the native CDs (Figure 2). The first enantioseparations with CDs were carried out in 1985 as an extension to isotachopheresis, where the CD was added to the leading buffer. However Fanali is credited with one of the first uses of β -CD for the resolution of ephedrine alkaloids by CZE.

With a better understanding of the implications of chiral compounds in everything from the chemical to food and pharmaceutical industries, stereospecific synthesis has developed to a point where very few racemic compounds will be used in the future. However, the analyst still has a role to play in checking the enantiopurity of the synthetic product. Detection levels are regularly at < 0.5% m/m and the order of migration can often dictate whether low enantiomer levels are detected. Most favourable conditions generally exist when the minor enantiomer precedes the major component. One option to control the migration order is to operate with anionic, cationic or neutral coated silica capillaries. A typical example is shown in Figure 3 of a cationic coating, a polyamine on the surface and α -CD, which gives a limit of quantitation of < 0.05% m/m for D-tryptophan, in

Figure 1 Capillary-zone electrophoresis resolution with β -cyclodextrin (β -CD) of the drug nomifensine maleate (65 mg L^{-1}) which has the hydrophobic group close to the chiral centre. The buffer was 20 mmol L^{-1} sodium tetraborate (pH 12.5) containing 20 mmol L^{-1} β -CD. The capillary was 37 cm (30 cm to detector) \times $50 \text{ }\mu\text{m}$ i.d. The applied voltage was 20 kV, detection wavelength 284 nm and temperature 30°C .

Figure 2 The resolution of oxamniquine by capillary-zone electrophoresis with neutral cyclodextrins. Resolution was at pH 2.25 with hydroxypropyl β -CD, but there was no resolution with β -CD at this pH. The β -CD gives resolution at pH 12, but with reversed migration order. (A) 50 mmol L⁻¹ disodium hydrogen phosphate (pH 12) with 25 mmol L⁻¹ β -CD; applied voltage 15 kV; (B) 50 mmol L⁻¹ sodium dihydrogen phosphate (pH 2.25) containing 40 mmol L⁻¹ hydroxypropyl β -CD; applied voltage 20 kV. The temperature was 30°C and detection wavelength 246 nm.

the presence of the L-enantiomer. During these runs the polarity is reversed over the conventional direction of operation. The coated capillaries mentioned above are commercially available and have been shown to be stable if used within the suggested limits. The anionic (sulfonic acid) coated capillaries are of particular interest in chiral and conventional separations as they give a consistent EOF over the range pH 3–9 and therefore are more controlled in operation.

Crown Ethers

Crown ethers act in a similar manner of enantiomer inclusion as CDs and contain a central cavity, although the mechanism is based on ionic and hydrogen bonding. They are macrocyclic polyethers, soluble in both aqueous and organic solvents, which form stable complexes with enantiomers, which have a primary amine or alkylamine functionality. For resolution, differential stability of the host–guest complex is required. This is reliant on the spatial arrangement between the amine and its hydrogen bonds with the ether oxygens. 18-Crown-6-tetracarboxylic acid is the easiest to obtain commercially and has been used to resolve a number of primary amines and racemic amino acids on a silica capillary, by addition of the crown ether into the buffer phase at low concentration, under CZE conditions. By this means a few chiral separations have been achieved which have not been fully successful by other means, such as chiral peptides. Crown ethers have also been used in combination with CDs for complex mixtures. In general, however, crown ethers have not been

Figure 3 Detection of D-tryptophan at 0.05% m/m in L-tryptophan (LOD ($3 \times s/n$) 0.01% m/m) with a polyamine coated capillary (eCAP™ with polyamine regeneration solution) to give a positive charge on the capillary. Capillary was 37 cm (30 cm to detector) \times 50 μ m fused silica and buffer 40 mmol L⁻¹ tris-phosphoric acid containing 75 mmol L⁻¹ α -CD. The applied voltage was -10 kV, detection wavelength 241 nm, injection time 2 s and operating temperature 30°C.

extensively used because they need to be applied under controlled conditions as they are highly toxic and they are limited to amines and alkylamines. However, in the applications reported they give highly efficient resolutions of certain chiral compounds.

Other Chiral Additives

Apart from the CDs, linear oligosaccharides are potential chiral discriminators in CE, and maltodextrin mixtures, corn syrups and pure malto-oligosaccharides have all been used to resolve non-steroidal anti-inflammatory drugs (NSAIDs). Polysaccharides have also been discussed in these reports, with applications of heparin, a naturally occurring mammalian mucopolysaccharide (anticoagulant), in the resolution of chiral drugs. The molecule is chiral, highly anionic and helical and has been used in the chiral discrimination of antimalarials and antihistaminics. In **Figure 4**, oxamniquine is resolved with a large resolution factor with 2% w/v heparin. Thus heparin and some of the other polysaccharides with their high separation efficiencies appeared to be good alternatives to CDs. There is one drawback: because of their heterogeneous character, batch-to-batch and different source material can result in changes in the resolution and therefore method robustness would be questionable for regular assay for industry.

Proteins provide another alternative based on successes in HPLC and particularly separations with α_1 -acid glycoprotein (AGP) and bovine serum albumin (BSA) for chiral drug separations. BSA has

been cross-linked with glutaraldehyde to form a polymer matrix. However, BSA has a high ultraviolet background and as such needs to be used in indirect detection mode or where the gel is only partially loaded on to the capillary and stops just before the detection window. AGP, ovomucoid (egg white) and fungal cellulose have all been used, with some success. The major problem with the fungal cellulose is absorption on to the capillary wall if used with uncoated capillaries, although adding materials such as polyethylene glycol or methyl cellulose into the electrolyte does alleviate wall interaction.

Micellar Electrokinetic Capillary Chromatography

Neutral compounds present a problem in CE since they have no differential mobility because of their lack of charge and are carried without separation by the EOF. One solution is to operate with surfactants, which form micelles above a certain concentration, and then differentiate between the compounds on the basis of both electrophoretic migration and micellar partitioning. This technique has been so successful that it is now one of the commonest procedures used in CE. Initially the emphasis was on achiral compounds, but it was quickly extended to chiral compounds by the introduction of either chiral surfactants or chiral additives, such as CDs. Surfactants are long chain molecules, characterized by a hydrophobic tail pointing inwards and a hydrophilic head pointing outwards into the aqueous buffer. Micelles are amphiphilic aggregates of surfactant molecules which form above a surfactant concentration, known as the critical micelle concentration (CMC) (**Table 1**). There are four classes of surfactants – anionic,

Figure 4 The resolution of oxamniquine by capillary-zone electrophoresis with heparin in the electrolyte solution. The electrolyte was 50 mmol L⁻¹ sodium dihydrogen phosphate (pH 3.0) containing 2% m/v heparin. The capillary was 71 cm (50 cm to detector) \times 50 μ m i.d., the applied voltage 20 kV, temperature 30°C and the detection wavelength 246 nm.

Table 1 The critical micelle concentrations of chiral surfactants and achiral surfactants

Surfactant	Critical micelle concentration (mmol L ⁻¹)
<i>Chiral</i>	
Sodium cholate	14
Sodium taurocholate	13
Sodium deoxycholate	5
Sodium taurodeoxycholate	4
Sodium <i>N</i> -dodecanoyl-L-valinate	6 (40°C)
<i>Achiral</i>	
Sodium dodecyl sulfate (SDS)	8
Sodium decane sulfate	40
Tetradecyltrimethylammonium bromide (TTAB)	4
Cetyltrimethylammonium bromide (CTAB)	1

cationic, zwitterionic and nonionic – which can be both synthetic and naturally occurring. The synthetic group includes the anionic sodium dodecyl sulfate (SDS) and cationic cetyltrimethylammonium bromide (CTAB).

A slightly different process, microemulsion electrophoretic chromatography, has recently been developed. In this process a combination of oil–water–surfactant and co-surfactant such as an alkyl chain alcohol is used as a pseudo-stationary phase.

Chiral Surfactants

These can be synthetic optically active amino acid derivatives and natural surfactants, such as glycyrrhizic acid, β -escin, bile salts and digitonin. Digitonin is nonionic, but has been used as a mixed micelle with SDS to give the electrophoretic mobility, to resolve chiral amino acids. These materials are generally water-soluble and can be added easily at micelle concentrations to the electrolytes in MEKC, although viscosity increases should be noted. Initially enantiomeric separations were directed towards neutral chiral compounds such as benzoin, and warfarin, a heart drug, which were selectively resolved with materials such as sodium *N*-dodecanoyl-L-valinate (SDVal) and *N*-dodecanoyl-L-glutamate (SDGlu). But it was soon realized that charged chiral compounds could also be resolved. Sodium taurocholate (STC) or the taurodeoxycholate (STDC) has been used under acidic conditions for the resolution of dansylated-DL-amino acids and for carboline derivatives and 2,2'-dihydroxy-1,1'-dinaphthyl used under neutral conditions for the drug diltiazem (Figure 5).

Chiral Selector with an Achiral Surfactant

This mode can give added selectivity to resolution of both neutral and charged chiral molecules, as the solutes are distributed between chiral selector such as a CD, the aqueous phase and the micelle (Figure 6). As a result, the chiral analytes will move in and out of the micelle/CD, with the CD moving with the EOF and the micelle (depending on polarity) moving according to charge. Racemic amino acids, β -blocker drugs, Trogers base and the drug terbutaline have all been resolved with this procedure. In the case of terbutaline either 5 mmol L⁻¹ di-O-methyl- β -cyclodextrin or 15 mmol L⁻¹ β -cyclodextrin was successfully used with 15 mmol L⁻¹ SDS. Other approaches have been to carry out competitive separations with CD-MEKC, where an additive, such as D-camphor-10-sulfonate, is introduced into the buffer and competes for inclusion with the chiral analytes. With this procedure an improved resolution of Trogers base was obtained. Overall, this form of

Figure 5 The use of bile salts to resolve the enantiomers of diltiazem and related substances by chiral micellar electrokinetic chromatography (MEKC). The electrolyte was 20 mmol L⁻¹ disodium hydrogen phosphate–sodium tetraborate (pH 7.0) containing 50 mmol L⁻¹ sodium taurodeoxycholate. The capillary was 65 cm (50 cm to detector) \times 50 μ m i.d. Applied voltage was 20 kV, detection wavelength was 210 nm and temperature was 25°C.

separation of chiral analytes has become quite popular, particularly as there are many derivatized CDs to choose from, and many examples have been published. Of the native CDs, γ -CD has shown the greatest success, which is the opposite of the case with the conventional addition of CDs to the buffer phase. In this case the larger inner diameter of the cavity of the γ -CD allows not only the chiral molecules to be included but also the surfactant.

Capillary Electrochromatography (CEC)

There is much current interest in electrochromatography, which is a hybrid technique between HPLC and CE, operating with packed capillaries. It is based on partitioning the analytes between the stationary phase (in packed capillaries) and the mobile phase (electrolyte) under CE conditions with a high applied voltage. The procedure benefits from the large range of HPLC stationary phases and some specific phases which are beginning to be developed for CEC. It links the high efficiency of CE with the range of separations possible with reversed-phase HPLC. For transport of the analytes in CEC, EOF is still present, but now the effective EOF is mainly generated from the packed bed of stationary phase rather than at the walls of the capillary. This results from the electrical double layer

Figure 6 Schematic of the chiral analyte 5-alkyl-5-phenyl hydantoin distributed between the cyclodextrin, the aqueous phase and the micelle. SDS, Sodium dodecyl sulfate.

on the surface of the particles in contact with the mobile phase and produces a ζ potential. The potential of CEC was first demonstrated in 1987, showing the presence of the partitioning effects and, for charged analytes, the continued effect of electromigration. In terms of the separation conditions in CEC and HPLC, the stationary and mobile phases are very similar, but the separation efficiency can be much improved. Many applications of electrochromatography are currently being studied and the range of capillary packing materials continues to expand.

Chiral stationary phases are being examined by a number of researchers. In one of the first reports of chiral separations by CEC 5 μm AGP, immobilized on to silica, was packed into a 50 μm internal diameter capillary. Cationic and neutral enantiomers were resolved by this method, which included benzoin and the drugs cyclophosphamide and hexobarbital. This early work did not illustrate large improvements in peak efficiency over other procedures as the capillary packing methods required improvement, but it did illustrate the potential.

CDs have also been used as immobilized silica-based materials and the neutral CD hydroxypropyl- β -CD silica was used in resolution of the basic drug mianserin. In method design with the CDs, the choice of the background electrolyte has played an important part and pH, organic modifier and differences in field strength have all been considered. The direction of flow past the detector was shown to be dependent on the background electrolyte used. For β -cyclodextrin and a phosphate buffer the direction of flow is

towards the cathode, but with triethylammonium acetate the flow is reversed. This can be beneficial in controlling the order of retention in CEC. The pH change in the electroosmotic mobility can be used to obtain a suitable overall retention time. Organic modifiers such as methanol and acetonitrile in the electrolyte have an effect on both the retention and enantioselectivity. The results from studies with CD-bonded silica phases indicate that a range of parameters and additives can affect the retention and enantioresolution in CEC, as they do with chiral stationary phases in HPLC.

Other stationary phases which have been shown to give enantioseparations are the cellulose and amylose derivatives which have been coated on to silica. These stationary phases are known as Chiralcel and Chiralpak phases (Daicel, Japan), respectively. These materials have been successful in HPLC for enantioselectivity with a wide range of chiral compounds and have recently been utilized as packing materials for CEC (Figure 7). Generally in CEC good resolution has been achieved for a number of chiral compounds resolved by HPLC, with improvements in separation efficiencies in many cases.

Future Developments

Capillary electrophoresis has had a major impact on the resolution of chiral compounds by the methods discussed above. The method is now regularly used to assay enantiomeric compounds in many fields with generally better efficiency than in HPLC and with

Figure 7 Electrochromatographic resolution of methylphenyl barbitone by a Chiralcel OJ (Daicel, Japan) chiral stationary phase. The cellulose ester derivative commercially coated on to silica was packed into a 30 cm (21 cm packed and 22 cm to detection window) \times 75 μ m i.d. fused silica capillary. The mobile phase was acetonitrile–water (70 : 30 v/v), applied voltage 15 kV and temperature 25°C.

shorter overall migration times. Many different areas are showing considerable research interest, such as electrochromatography, where in the future commercially available columns may prevail over in house methods of packing capillaries with chiral stationary phases. Generally, commercial interest in the area of capillary packings is likely to increase as more ‘tailor-made’ phases are introduced.

Cellulose and Cellulose Derived Phases

Introduction

The properties of cellulose derivatives for the separation of enantiomers were recognized in 1966 by Lüttringhaus and Peters. The full potential of microcrystalline cellulose triacetate (CTA) was definitely established by Hesse and Hagel in 1973. Meanwhile,

microcrystalline cellulose tribenzoate became commercially available. Another milestone in the development of cellulose- and amylose-based phases was the work of Okamoto and co-workers who in 1984 introduced polysaccharide derivatives coated on a macroporous silica. Currently such materials are certainly the most universally applicable type of commercially available chiral stationary phases. Then, in 1988 Francotte and co-workers introduced cellulose esters of aromatic acids in the form of almost spherical, partially crystalline particles with a relatively

good mechanical stability. The last few years have also seen a lot of research in grafting cellulose and amylose derivatives on to a silica matrix.

Recently, different types of polysaccharide phase (Chiralcel AD, Chiralcel AS, Chiralcel OD and Chiralcel OJ) wall-coated open tubular (WCOT) columns have also been used for supercritical fluid chromatography applications.

Here, the properties and possibilities of different types of polysaccharide phases used for enantiomer separation are discussed.

Microcrystalline Cellulose Triacetate

By a heterogeneous acetylation procedure, cellulose can be acetylated so that the mutual arrangement of the carbohydrate chains within their crystalline regions is maintained. CTA obtained by this acetylation technique has only weak chiral recognition abilities. Only in its swollen state is triacetyl cellulose capable of separating enantiomers. An ethanol–water (95 : 5, v/v) mixture is the most frequently used swelling agent for CTA. When dry CTA is boiled for 15 min in the ethanol–water mixture, a volume increase of about 40% is observed.

Microcrystalline CTA is a material that can be used to separate a broad variety of enantiomers belonging to many different classes of organic compounds (thiazoline-2 thiones, barbiturates, hydrocarbons, oxiranes, flavanones, γ - and δ -lactones, metal complexes, etc.) Its high loading capacity makes it an extremely useful material for preparative chromatographic purposes.

Mobile-Phase Design

A lot of different solvents, e.g. acetone, chlorinated alkanes and acetonitrile, cannot be used because they dissolve CTA more or less completely. In tetrahydrofuran, CTA forms a gel. In some other solvents, like for example, 1,4 dioxane and dimethoxyethane, CTA swells too strongly. Different investigators found as a general rule that the retention factors of the investigated analytes increased when, respectively, methanol, ethanol or propanol was used as the eluent. However, the highest selectivity factors are often found with ethanol as the eluent. Successful separations are also obtained by using other low molecular weight alcohols, ethers, hydrocarbons and mixtures of these eluents. Examples are methanol-2-propanol (80 : 20; v/v); ethanol-*tert*-butyl methyl-ether–water (86 : 10 : 4, v/v) and *n*-hexane-2-propanol–water (70 : 27 : 3, v/v).

In general, a significant influence on the retention factor and enantioselectivity is observed when ethanol as the eluent is modified with methanol, 2-

propanol, different amounts of water, or is completely replaced by methanol or 2-propanol.

If compounds bearing an ionizable group have to be analysed, buffer systems should be tried. CTA seems to withstand the use of buffers in the range between pH 5 and 10 for a long time without any significant loss of chromatographic properties. Eluents with a high water content at high or low pH values should be avoided because CTA can be hydrolysed under these conditions.

Empirically, it has been found that, on CTA successful enantiomer separations can be expected if the analytes possess an aromatic or nonaromatic ring close to the chiral centre or if the products have an asymmetric atom on a rigid ring structure.

Also it is known from experience that compounds bearing an ionizable group, like for example, a hydroxyl, carboxyl or amino group, are generally poorly resolved on CTA.

Derivatization of these functional groups into the corresponding ester, amide or carbamate derivative often improves the selectivity. For alcohol, an esterification reaction with a *P*-substituted benzoic acid chloride (F, Cl, Br, CN, NO₂, OCH₃) has been successfully applied to solve a number of different separation problems.

CTA is attractive for chiral separations because it can be synthesized from a low cost natural product. The wide range of products that can be separated, together with its high loading capacity, certainly makes it a material that should be considered as a valuable tool in the development of chiral separation methods. Besides the usefulness of CTA in the field of enantiomer separations, this material is also suitable for the separation of positional isomers.

Microcrystalline Cellulose Tribenzoate

As early as 1969, Safanova and Klenkova had described the heterogeneous benzylation of microcrystalline cellulose. Rimböck *et al.* later described a method for preparing this material using an ultrasonic field to accelerate the reaction. Nowadays, a methanol–water solution containing about 40% of the pre-swollen material is commercially available.

Comparable with CTA, different solvents or solvent combinations also cause different degrees of swelling of this material. Dichloromethane or tetrahydrofuran cannot be used as the eluent because tribenzoylcellulose is soluble in these solvents.

With microcrystalline cellulose tribenzoate, a stationary phase for chromatographic enantiomer separations has been introduced, which allows the resolving of different classes of organic compounds.

Cellulose tribenzoate, compared to some other types of chiral stationary phases, offers the advantage that, besides analytical separations, preparative work can also be performed without a great deal of effort.

Benzoyl Cellulose Beads (in the Pure Polymeric Form)

Francotte and co-workers developed this type of chiral stationary phase. These materials are cellulose esters of aromatic acids in the form of almost spherical, partially crystalline particles with a good mechanical stability.

To characterize these phases, a broad variety of product classes on experimental batches of benzoyl- and *p*-methylbenzoyl cellulose beads have been examined. Methanol, ethanol and *n*-hexane-2-propanol were used as the eluent and the results obtained were compared with data measured under the same experimental conditions on the corresponding physically coated materials (Chiralcel OB and Chiralcel OJ).

In general, much higher retention values are observed on the pure cellulose derivatives compared to the values measured on the corresponding coated stationary phases. This observation is logical, because the physically coated phases only contain about 20 weight percent of the cellulose derivative. For the investigated product series, in most cases smaller retention values were measured for methanol than for ethanol as the mobile phase. Furthermore, most products also demonstrated the highest resolution values when methanol was used as the eluent.

For some of the substances tested, practically no difference in resolution was observed between the pure cellulose material and the coated phases, while other product classes were always better separated on the commercially available columns.

Mobile-Phase Effects

A chromatogram of the Mesuximid enantiomer separation that clearly illustrates the separation power of this type of materials is depicted in **Figure 1**.

For Mesuximid, using *n*-hexane-2-propanol as the mobile phase, the investigation of the effect of the polar modifier concentration on the retention factor demonstrate that, below a certain polar modifier concentration, the retention factor strongly increases. This can be an indication that competition between the polar modifier and the solute for hydrogen-binding sites on the stationary phase might be the determining factor in the retention process.

Although the retention factor is strongly influenced by the polar modifier concentration, the effect on the

Figure 1 Benzoyl cellulose beads in the pure polymeric form: effect of polar modifier concentration on the retention factor. Column: 125 × 4 mm i.d. filled with 10 μ m *p*-methylbenzoyl cellulose beads. Mobile phase: *n*-hexane-2-propanol in different ratios. Flow rate: 1 mL min⁻¹. Sample: Mesuximid.

selectivity factor in the studied range of polar modifier content remains rather small.

The benzoyl cellulose derivatives in the pure polymeric form allow the separation of a broad variety of compounds. In many cases, results are obtained which are comparable with the values measured on the corresponding physically coated phases. Furthermore, these materials are very useful as stationary phases for preparative chromatographic applications.

Physically Coated Cellulose and Amylose Derivatives

This type of chiral stationary phase, developed by Okamoto and commercialized by Daicel Chemical Industries, can be considered to be the most universally applicable type of chiral stationary phase for both analytical and preparative chromatographic applications. Many different column types are available on the market. However, experience suggests that, with four different types of phases, a wide range of racemates, belonging to a broad variety of product classes, can be separated. The most interesting phases in our view are:

1. Cellulose derivatives:
 - (a) Chiralcel OD (3,5 dimethylphenyl carbamate derivative)
 - (b) Chiralcel OJ (*para*-methylbenzoyl derivative)
2. Amylose derivatives:
 - (a) Chiralpak AD (3,5 dimethylphenyl carbamate derivative)
 - (b) Chiralpak AS [(*S*)- α -methylbenzyl carbamate derivative]

The analytical phases are coated on a 10 μ m wide pore silica. However, some types of phases are also available on a 5 μ m silica matrix. Furthermore, two phases, which are specifically designed for reversed-phase applications, have been brought on to the market. An overview of the different types of commercially available coated phases is given in **Table 1**.

Table 1 Commercially available silica-coated phases for enantioseparation

<i>Cellulose esters</i>	<i>Type of absorbent</i>
Chiralcel OJ	<i>p</i> -Methylbenzoyl
Chiralcel OJ-R	For reversed-phase application
Chiralcel OB	Benzoyl
Chiralcel OB-H	Coated on a 5 μ m silica matrix
Chiralcel OA	Acetyl
Chiralcel OK	Cinnamoyl
Chiralcel CA-1	Acetyl
<i>Cellulose carbamates</i>	
Chiralcel OD	3,5-Dimethylphenyl
Chiralcel OD-H	Coated on a 5 μ m silica matrix
Chiralcel OD-R	For reversed-phase applications
Chiralcel OD-RH	For reversed-phase applications
Chiralcel OC	Phenyl
Chiralcel OG	<i>p</i> -Methylphenyl
Chiralcel OF	<i>p</i> -Chlorophenyl
<i>Amylose carbamates</i>	
Chiralpak AD	3,5 Dimethylphenyl
Chiralpak AS	(<i>S</i>)- α -Methylbenzyl

Mobile-Phase Design and Parameter Optimization

Different investigators have suggested that the mechanism of chiral recognition on cellulose and amylose derivatives is based on:

1. Hydrogen bonding
2. Dipole-dipole interaction
3. Charge transfer complex formation (π - π interactions)
4. Possible inclusion into chiral cavities or channels of the chiral stationary phase

Whatever the type of interaction involved, the mobile phase must be considered as a dynamic part of the system, capable of interacting with both the enantiomeric solute and the chiral stationary phase. For solutes where hydrogen bonding plays an important role in the selective chiral interaction process, proton-donating polar modifiers can compete with the solute for the hydrogen-bonding sites of the stationary phase. In other cases, π - π interactions between an aromatic moiety on the solute and the chiral stationary phase seems to be the most important interaction force.

Most of the separations on physically coated cellulose and amylose columns have been performed with mobile phases consisting of *n*-hexane or *n*-heptane as the major component, mixed with various aliphatic alcohols. The choice of solvent combination is principally based on recommendations for use by the manufacturer. Concerns about the stability of these columns combined with the relatively high cost

discouraged the use of other solvent combinations than those recommended by the manufacturer. However, in the last few years, other aprotic solvents, e.g., acetonitrile, methyl-tertiary-butyl ether and ethyl acetate have been applied on certain types of the derivatized polysaccharide columns. Certainly in the field of preparative chromatographic enantiomer separations. These alternative solvents widen the application range of this type of stationary phase.

For method development on this type of phase screening experiments on 50 \times 4.6 mm ID pre-columns filled with respectively Chiralcel OJ, Chiralcel OD, Chiralpak AD and Chiralpak AS are convenient. In use such column are rapidly equilibrated, give fast separations and have in many cases more than sufficient separation power for initial method development work. As a general rule, pure ethanol at a flow rate of 0.5 mL min⁻¹ is used as the eluent of choice to perform the first experiments.

Pure ethanol is chosen based on the experience that, for a lot of products, below a certain amount of polar modifier in an *n*-hexane or *n*-heptane based mobile phase, the retention factors strongly increase. In general, the effect of the polar modifier on the retention factor decreases upon increasing modifier content. An indication that the competition between the solute and the polar modifier in the eluent for the hydrogen-bonding sites of the stationary phase is a saturable process and a maximum effect on the retention factor will be reached within a certain range of polar modifier concentration (for our type of compounds, mostly situated between 15 and 20%). If, in the screening experiments, the analytes are insufficiently retained or no separation is observed, ethanol is mixed with *n*-heptane or *n*-hexane in different ratios. Once a suitable *n*-heptane-ethanol ratio has been found to reach a *k'* value between 3 and 6, ethanol is replaced by the same molar amount of one of the other lower aliphatic alcohols (1- or 2-propanol, primary, secondary or tertiary butanol). In many cases, large effects on the resolution values can be observed when ethanol as polar modifier is replaced by another alcohol.

Experience shows that pure methanol or mixtures of ethanol and methanol or ethanol and 2-propanol are often very useful to improve a separation.

On these phases it has been observed that the retention factors of a range of 2,3-dihydro-1,4-benzodioxin-2-carboxylic acid esters increased with increased chain length of the alcohol used for chromatography on a Chiralcel OB column. This effect might be based on a reduced capability of the larger alcohols to compete with the solute for hydrogen-binding sites on the stationary phase.

The higher retention values measured for the branched alcohols compared to their corresponding linear analogues may be due to steric influences, which result in a reduced tendency of these alcohols to interact by hydrogen bonding with the polysaccharide phase.

The observed decrease in retention factor with increasing chain length of the ester group could be an indication that hydrophobic effects also contribute to the interaction mechanism between the solute and the chiral stationary phase.

For the lower members of the homologue series of the 2,3-dihydro-1,4-benzodioxin-2-carboxylic acid esters, practically no difference in resolution values can be observed between the different polar modifiers. Depending on the type of alcohol used, the resolution rapidly decreases for the pentyl ester and the higher homologues. Only for *n*-butanol as polar modifier, is the decrease in resolution value rather limited. For ethanol the lowest resolution values are observed for the whole product series. There are indications that, for the investigated solutes, hydrogen-bonding forces certainly play an important role in the chiral recognition process.

This type of experiment clearly demonstrates that, when *n*-hexane or *n*-heptane-alcohol mixtures are used, testing different alcohols as polar modifier during method development should be performed, because in many cases, large differences in enantioselectivity may be observed.

It is also interesting to note that, by changing the polar modifier phase, an inversion of the elution order can occur, as illustrated in the following example. On a Chiralcel OD column, it was possible to separate the investigated compound (R89439) in its two enantiomers using a mixture of *n*-hexane-ethanol in an 80 : 20 volume ratio. The desired enantiomer eluted as the first peak under these experimental conditions, as illustrated in **Figure 2A**. When the ethanol as polar modifier was partially replaced by methanol, a reversal of elution order was observed, as illustrated in **Figure 2B**.

Some investigators have suggested that binding a polar modifier to sites near the chiral cavities might alter the steric environment of these cavities. If the environment of these cavities changes, it can certainly have an influence on the steric fit of the chiral solutes in these cavities, which may in part be responsible for the observed phenomenon of reversal in elution order. It is furthermore interesting to note that a reversal of elution order can often be achieved by the changeover of a carbamate-type phase towards a benzoate-type phase. This knowledge can be very useful when a small amount of one enantiomer has to be determined besides a large excess of the other enan-

tiomer, because it is easier to quantify a small peak in front of a large one than in the opposite situation. Based on experience, it is also important to mention that sometimes even small variations in experimental conditions can have a tremendous effect on the resolution of enantiomers on this type of stationary phases.

The often observed strong influence of small differences in experimental conditions on the resolution, certainly has to be considered when robust and reproducible methods have to be developed on this type of phases, for regulatory (Good Laboratory (GLP), Good Manufacturing (GMP)) purposes.

An example of the use of aprotic modifiers, which can also affect the separation on these phases, is as follows. About 40 g of a diastereomeric mixture had to be separated into its four enantiomers. Very good separation was obtained on an amylose 3,5-dimethyl-phenyl carbamate (Chiralpak AD) column using pure ethanol, pure methanol or a mixture of ethanol and 2-propanol in a 90 : 10 volume ratio. Unfortunately, the solubility of the diastereomeric mixture in the alcohol used was very poor. We therefore decided to study the behaviour of ethanol-acetonitrile mixtures, because the solubility of the product was a lot better in acetonitrile.

The results of these experiments are summarized in **Table 2** and graphically represented in **Figure 3**.

As illustrated in **Figure 3**, the addition of an aprotic modifier to the polar organic solvent has a clear effect on the retention behaviour and the enantioselectivity, especially for the most retained enantiomers. The investigated solute molecule contains different hydrogen-bonding groups, which can strongly interact with the carbamate functionality of the stationary phase. Combined with poor solubility of the substance in the lower molecular weight alcohols, this makes these solvents less suitable to displace the solute from the stationary phase and probably explains the high retention values observed for pure methanol or ethanol.

The addition of acetonitrile improves the solubility of the product. This at first simplifies the transfer of the solute into the mobile phase and furthermore gives the protic solvent a better chance to compete for the hydrogen-bonding sites of the stationary phase, which may explain the observed systematic decrease in retention factors with increasing acetonitrile concentration. Below a certain concentration of protic solvent in the eluent, the strong hydrogen-bonding properties of the solute predominate again, resulting in an increase in retention factor. Using a mixture of ethanol and acetonitrile in a 30 : 70 volume ratio allowed the separation of the diastereomeric mixture in its four enantiomers without difficulty.

Figure 2 Effect of mobile-phase composition on the elution order. Column: 250 × 4.6 mm. Chiralcel OD (cellulose 3,5 dimethylphenyl carbamate). Mobile phase: (A) *n*-hexane–ethanol (80 : 20; v/v); (B) *n*-hexane–ethanol–methanol (80 : 5 : 15; v/v). Flow rate: 1 mL min⁻¹. Sample: R89439 (racemate plus pure enantiomer).

Table 2 Effect of the addition of acetonitrile on retention behaviour and enantioselectivity

Acetonitrile (%)	<i>k'</i> 1	<i>k'</i> 2	<i>k'</i> 3	<i>k'</i> 4	α (1–2)	α (3–4)

80	1.31	2.67	16.86	27.0	2.038	1.601

Basic or acidic additives can also have major effects on the separations. Thus, for some basic or acidic substances, it is often necessary to add respectively a base or an acid to improve the peak shape. Based on the manufacturer's recommendations, it is possible to use up to 1% of di- or triethylamine to reduce the tailing of basic substances. Acetic or trifluoroacetic acid can be used for the analysis of acidic substances.

The usefulness of these mobile-phase additives, is shown in the following example. For the enantiomer separation of [(±) 2,6-dichloro- α -(4-chlorophenyl)-4-(4,5-dihydro-3,5-dioxo-1,2,4-triazin-2-(3H)-yl) benzene acetonitrile] (diclazuril) initially a method was used in which the acidic NH-group in the 3,5-dioxo-1,2,4 triazin part of the molecule was methylated with diazomethane. The derivatized product

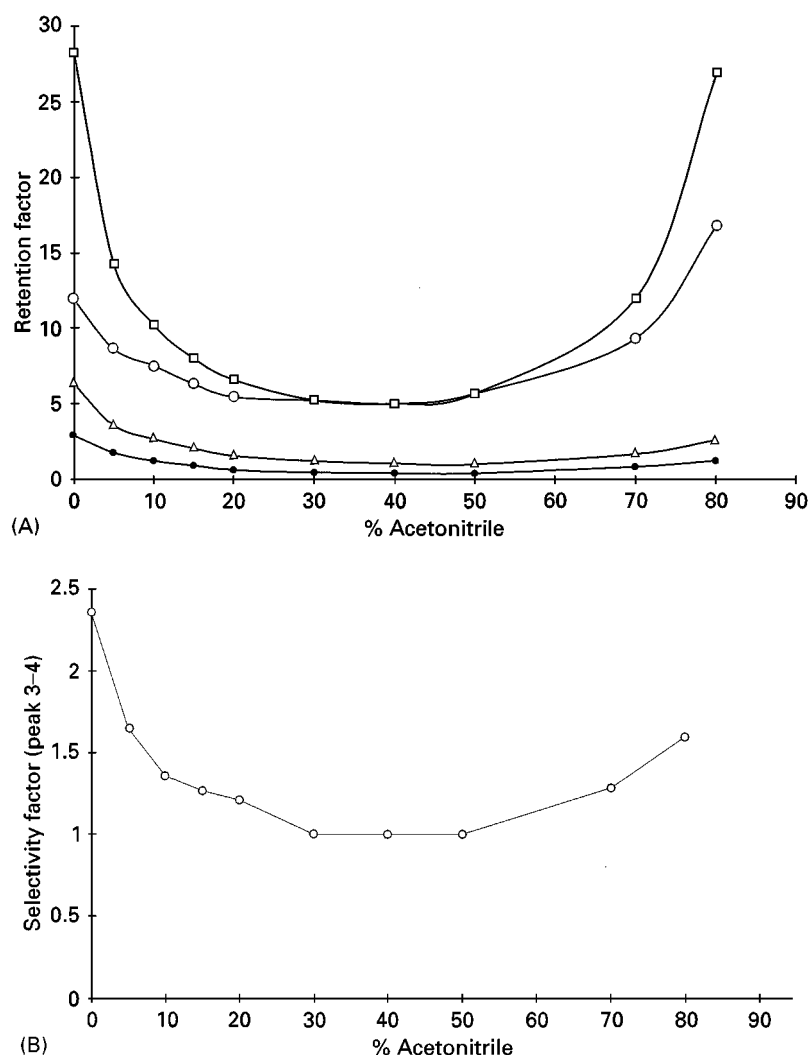

Figure 3 Effect of acetonitrile on (A) the retention factor; (B) enantioselectivity. Column: 250 \times 4.6 mm Chiralcel AD (amylose 3,5 dimethylphenyl carbamate). Mobile phase: ethanol-acetonitrile in different ratios. Flow rate: 1 mL min⁻¹. Filled circles, k'_1 ; triangles, k'_2 ; open circles, k'_3 ; squares, k'_4 .

could easily be analysed on an amylose 3,5 dimethylphenyl carbamate (Chiralpak AD) column, using ethanol-*n*-hexane in an 80 : 20 volume ratio.

A chromatogram of this separation is illustrated in Figure 4A.

As can be seen from Figure 4A, reaction with diazomethane results in different reaction products, with both nitrogen alkylated and oxygen alkylated compounds observed. Because direct analysis of this product on the cellulose- or amylose-based stationary phases, using the classical eluents, was not possible, due to the presence of the acidic NH-group in the 3,5-dioxo-1,2,4-triazin part of the molecule (which resulted in a retardation of the substance on the stationary phase), the effect of the addition of trifluoroacetic acid was examined. The result of such an

experiment on a micro-LC column is shown in Figure 4B.

The use of an amine as tailing reducer is illustrated in the following example. A few grams of a chiral amino alcohol had to be separated in its two enantiomers. Only partial separation could be obtained on a Chiralcel OD (cellulose 3,5-dimethylphenyl carbamate) column using a mixture of *n*-hexane and 2-propanol in a 70 : 30 volume ratio. Because a severe tailing was observed, we investigated the effect on the addition of triethylamine as mobile-phase additive. A small quantity of 0.1 vol% of triethylamine improved the peak shape and the resolution. However, a much better result was observed when the triethylamine content was increased to 0.5 vol%. Thereafter, triethylamine was replaced for the same

Figure 4 (A) Separation of diclazuril after derivatization with diazomethane. Column: 250×4.6 mm i.d. Chiralpak AD (amylose 3,5 dimethylphenyl carbamate). Mobile phase: ethanol-*n*-hexane (80 : 20; v/v). Flow rate: 0.5 mL min^{-1} . Detection: UV (290 nm). Injection volume: $10 \text{ }\mu\text{L}$. Temperature: ambient. Temperature: ambient.

amount of diethylamine. The addition of 0.5% diethylamine resulted in the highest resolution value.

Therefore, the first experiment on the preparative column was performed with a mobile phase containing 0.5 vol% of diethylamine. The obtained result was rather poor. The enantiomers eluted as relatively broad peaks, which were only partially resolved. Because for preparative chromatographic application we prefer to work with triethylamine instead of diethylamine, the method was therefore further optimized using triethylamine as tailing reducer. To reach

maximum resolution on the preparative column, the amount of 2-propanol had to be reduced from 30% to 10 vol%, while the triethylamine concentration had to be increased to 2 vol%.

Using this method, it was possible to inject 250 mg of the product. The optimized method enabled sufficient amount of the pure enantiomers to be prepared in a reasonable amount of time.

The solute structure will also clearly have a direct effect on the separation. Thus, the chiral recognition process on polysaccharide phases results from

differences in the summation of binding energies originating from:

1. hydrogen bonding
2. dipole-dipole interactions
3. charge transfer (π - π) complex formation
4. steric interactions

It is not possible to generalize which type of interaction forces plays the key role in the solute-chiral stationary phase complex formation. Hydrogen bonding certainly has a strong role in the selective chiral interaction process.

Based on the knowledge that on polysaccharide phases different mechanisms play a role in the chiral recognition process and small variations in experimental conditions or solute structure can strongly affect the enantioselectivity, it is clear that small changes in the molecular structure of a specific type of compounds that are in general well separated can often be a challenge to find an acceptable separation method for some of the members of such a product series.

The effect of small structural changes on the retention behaviour and the enantioselectivity is illustrated in the following examples.

In the first example, a few imidazole derivatives bearing an ester function on the imidazole ring were investigated on a Chiralcel OC (cellulose phenyl carbamate) as well as on a Chiralcel OD (cellulose 3,5-dimethylphenyl carbamate) column, using *n*-hexane-2-propanol as the mobile phase. On the Chiralcel OC column a mixture of *n*-hexane-2-propanol in a 90 : 10 volume ratio was used. Because with this mobile-phase composition the products were not sufficiently retained on the Chiralcel OD column, the amount of polar modifier had to be reduced to 5 vol% on this column type. On both column types the retention factor strongly decreased with increasing chain length of the ester group attached to the imidazole ring. Also steric effects seem to play a role, because on both columns the smallest retention value is measured for the 2-propyl ester.

When the resolution values are considered, a clear difference was to be observed between both column types. For the 1-propyl and 2-propyl esters, baseline resolution is obtained on both stationary phases. However, the observed differences for the ethyl and methyl ester are striking. On the Chiralcel OC column the ethyl ester is still baseline-resolved, while the methyl ester is only partially separated, whereas on the Chiralcel OD column, the methyl ester is very well separated and the ethyl ester did not display any separation at all. Certainly there is an indication that small but nevertheless influential contributions play

an important role in the chiral recognition process, which of course makes it not always that easy to predict whether a new product in a series of comparable structures will be separated or not on a particular type of stationary phase.

The next example also demonstrates that it is not always easy to predict whether a product within a series will be separated on a certain type of polysaccharide phase.

Some tetramisol derivatives were investigated on three different carbamate-type phases (Chiralcel OC, Chiralcel OF and Chiralcel OD) using *n*-hexane-2-propanol in a 70 : 30 volume ratio. For the investigated compounds, the highest retention is measured on the Chiralcel OF (*p*-chlorophenyl carbamate) column, while the smallest values are observed on the Chiralcel OD column. However, on the three different column types the *meta*-substituted derivative has always the most strongly retained.

Although the products were most strongly retained on the Chiralcel OF column, not one of the 10 investigated substances was fully baseline-resolved. Two of the *ortho*-substituted compounds and the unsubstituted tetramisol were best resolved on the Chiralcel OC column, while for the *meta*- and *para*-substituted derivatives the highest resolution value was in general measured on the Chiralcel OD column.

It is quite clear therefore from the different examples that small changes in solute structure or experimental conditions can have a strong influence on the chromatographic behaviour. This phenomenon makes it often difficult to predict whether a product will be separated on a certain type of polysaccharide phase or not. Therefore, even when a good mobile-phase composition has been found on a particular column, it is always advisable to test this solvent mixture on another column of the same type (carbamate or benzoate).

Achiral derivatization can be exploited to improve resolution as it is well known from experience that compounds bearing an ionizable group, e.g. a carboxyl, hydroxyl or amino group, are often poorly resolved on the polysaccharide type of phases. Derivatization of these functional groups to the corresponding ester, carbamate or amide derivatives frequently improves the separation.

For alcohol, for example, an esterification reaction with a *para*-substituted benzoic acid chloride has proven to be effective in solving difficult separation problems. The effect of an esterification reaction on the retention behaviour and the enantioselectivity is illustrated by means of the next examples.

The hydroxyl function of two completely different compounds was derivatized to yield the following

types of esters:

The different esters were respectively investigated on a Chiralcel OD, Chiralcel OJ, Chiralpak AD and Chiralpak AS column using pure ethanol as the eluent.

These compounds were retained more on the benzoate type of phase than on the carbamate type of stationary phase. Also, the resolution is significantly higher on the Chiralcel OJ column than on the other columns. The favourable results on the benzoate type of column inspired us to investigate the difference between ethanol and methanol as the mobile phase for this type of compound. For methanol much higher retention factors are measured than when ethanol is the eluent. In general, about twice as high resolution values are measured for methanol.

In the foregoing example, the best results for the different esters were obtained on a benzoate type of column. This is certainly not a general rule. Another alcohol [4,4-dimethoxy-1-(phenylmethyl)-3 piperidinol] was derivatized to yield a similar series of esters. This homologue series was also investigated on the four different types of polysaccharide phases, using ethanol as the eluent.

On the Chiralcel OJ column only the 2-naphthoyl derivative was partially separated. On the Chiralcel OD column only the 2-naphthoyl and the 9-anthracoyl ester were partially resolved, while on the Chiralpak AS column only the 9-anthracoyl ester showed partial resolution. However, on the Chiralpak AD column most of the products were separated. What is striking in this particular example is the partial separation of the native alcohol, while the benzoyl- and *p*-fluorobenzoyl esters do not show any separation at all.

For further synthesis applications, alcohols are frequently converted to the mesylated and tosylated derivative. When we are confronted with the preparative chromatographic separation of a racemic alcohol, we always investigate the mesylated or tosylated alcohol before carrying out other derivatization work, because we have experienced that in many

cases, these compounds are easier to separate than the native alcohol. For very difficult separations we eventually had to synthesize the naphthylsulfonyl derivative.

Temperature is well known to affect chiral isolation. Thus, on chiral stationary phases, specific interaction mechanisms are involved in the separation process. Therefore, this type of phase often displays slow mass transfer characteristics.

Temperature, together with the mobile-phase velocity, certainly has to be considered as a factor that can be used to influence this mass transfer process.

In the next example, we examined the combined effects of temperature and flow velocity variations on enantioselectivity, column efficiency and resolution. The enantiomers of the investigated racemate were difficult to separate. Only partial separation could be achieved with *n*-hexane-ethanol in a 90 : 10 volume ratio on a Chiralcel OJ column, using our standard experimental conditions of flow rate and temperature. To investigate this separation problem further, the temperature was varied between 5 and 40°C and flow rates between 0.25 and 2 mL min⁻¹ were tested.

A good linear relationship between the logarithm of the α value and the temperature has been observed. The α value steadily increased with decreasing temperature. However, the most significant parameter to indicate the separation between two products is the resolution value. This parameter is determined by both thermodynamic and kinetic contributions.

Although two completely different measuring principles have been used, comparable patterns are observed for the two resolution values. Both figures indicate that only for temperatures below 15°C and a flow rate of 0.25 mL min⁻¹ can a nearly baseline separation be obtained. Although it was not possible to obtain a full baseline separation of the enantiomers, the optimized analysis method was sufficiently accurate to follow up the investigations that were performed to develop a stereospecific synthesis method.

As this example indicates, during method development and optimization experiments, the factored temperature certainly has to be investigated. Besides essential information for analytical purposes, it also gives chromatographers performing preparative chromatographic separations a good idea of whether it is possible to work at higher temperatures without losing efficiency. Due to the limited choice of possible mobile-phase compositions, the major problem one has to deal with in preparative chromatographic work on polysaccharide phases is the solubility of the product to be separated in the eluent used. Because solubility in most cases increases with increasing temperature, the ability to work at higher temperatures

often improves throughput in preparative chromatographic separations.

The experiments performed also demonstrate that the flow velocity is a parameter that can be used to optimize a separation process.

Separation of Diastereomers

Although diastereomers are in general easy to separate under normal or reversed-phase chromatographic conditions, it often happens, especially when the chiral centres are located far away from each other, that it is not always easy to separate these compounds. When we are confronted with such a problem, we always investigate the possibilities of microcrystalline cellulose triacetate or tribenzoate and the physically coated derivatized polysaccharides. We have experienced that this approach can be a solution in many cases. An example of such a separation is described in the next example.

A racemic alcohol was derivatized with optically pure (1*S*)-camphor sulfonic acid chloride. It was not possible to separate the obtained diastereomers under normal-phase conditions on bare silica or amino-modified silica. Under the reversed-phase conditions which we generally apply in our laboratories it was not possible to separate the isomers. We did some experiments on different derivatized polysaccharide phases. On a 50 × 4.6 mm i.d. Chiralpak AD (amylose 3,5-dimethylphenyl carbamate) using ethanol as the

eluent, the diastereomers were very well separated. Because with pure ethanol the retention factors were relatively high, the effect of the addition of acetonitrile was investigated. A few chromatograms of these experiments are depicted in **Figure 5**. Using a mixture of 95 vol% ethanol and 5 vol% acetonitrile, it was easy to isolate a large pure amount of both diastereomers.

Reversed-Phase Applications

As mentioned before, two types of polysaccharide phases which are specifically designed for reversed-phase applications are currently on the market. This type of phase is extremely interesting for the direct injection of aqueous solutions (ionic products, plasma samples, etc.). Furthermore, the columns are useful in column-coupling techniques (for example, an octadecylsilica column followed by a polysaccharide column) to solve difficult separation problems. The manufacturer recommends on this type of column to use a mobile phase consisting of an aqueous solution of a sodium, ammonium or potassium salt in combination with methanol, ethanol or acetonitrile as the organic modifier. The choice of the cationic part of the salt seems not to have a significant effect on the separation. However, a significant difference in separation has been observed with various anions. Anions, such as ClO_4^- and PF_6^- in general show good separation. Also the salt concentration can strongly affect the retention time and the resolution.

Figure 5 Diastereomer separation. Column: 50 × 4.6 mm i.d. Chiralpak AD (amylose 3,5 dimethylphenyl carbamate). Flow rate: 1 mL min⁻¹. Mobile phase: 1, ethanol; 2, ethanol–acetonitrile (95 : 5; v/v); 3, ethanol–acetonitrile (90 : 10; v/v); 4, acetonitrile.

Mobile-phase design and parameter optimization

Triethylamine salts are very popular as tailing reducers in reversed-phase applications. We have therefore investigated the usefulness of these salts on the polysaccharide-type phases. Experience with cyclodextrin and derivatized cyclodextrin columns taught us that a salt concentration of 50 mmol L⁻¹ in general is high enough to obtain good peak shapes for basic substances. Experimental work was started with this salt concentration. Afterwards, specific experiments performed to investigate the effect of the tailing reducer concentration on the chromatographic parameters confirmed that 50 mmol L⁻¹ was a good choice. In a concentration range between 10 and 50 mmol L⁻¹ the highest resolution values were always measured for the highest salt concentration. However, this concentration also resulted in the strongest retardation of the compounds.

In a first set of experiments, the difference in chromatographic behaviour of a few products under normal-phase and reversed-phase conditions was investigated on a Chiralcel OJ-R and Chiralcel OD-R column. The columns were first equilibrated with ethanol. Thereafter, a mixture of *n*-hexane–2-propanol in a 70 : 30 volume ratio was pumped through the column until equilibrium was reached and the different products were analysed. After rinsing the columns with ethanol, the column was equilibrated with a mixture consisting of 70 vol% methanol and 30 vol% of a 50 mmol L⁻¹ triethylamine solution in water adjusted with sulfuric acid to a pH value of 2.5.

In general the products are better retained when reversed-phase conditions are applied. It was also striking that for most of the investigated products there was a large difference in resolution values between the two modes of operation.

Type of tailing reducer Experiments on cyclodextrin and derivatized cyclodextrin columns have shown us that, for the analysis of basic compounds, the anionic part of the tailing reducer has a clear effect on enantioselectivity. To investigate this effect, we selected some imidazole derivatives.

To perform the experiments, a 55 mmol L⁻¹ solution of triethylamine in analytical grade water was prepared and 2 L portions of this solution were adjusted to a pH value of 2.5 with respectively hydrochloric, trifluoroacetic, methanesulfonic, camphorsulfonic, sulfuric and phosphoric acid. After pH adjustment the solution was further diluted to obtain a solution which contains exactly 50 mmol L⁻¹ triethylamine.

As eluent a mixture composed of 70 vol% of methanol and 30 vol% of the triethylamine solution was used. On the Chiralcel OJ-R and on the Chiralcel

OD-R column, the retention values for phosphate or sulfate anion are markedly higher than the values measured for the other anions. The lowest values were in most cases measured for chloride as the counterion.

On both column types, the anionic part of the tailing reducer has a clear effect on enantioselectivity (Figure 6). In general, the best results are obtained for phosphate or sulfate as the anion, although for some products better results were obtained using another type of anion.

The Chiralcel OJ-R column is much more suitable for the separation of the investigated compounds than the Chiralcel OD-R column.

Type of polar modifier In experiments using a mixture of methanol and triethylamine in a 70 : 30 volume ratio, high retention times were observed for some compounds. Therefore, it was interesting to investigate the effect of the addition of acetonitrile on retention time and enantioselectivity. To perform these experiments, a mixture of 70 vol% methanol and 30 vol% triethylamine adjusted to pH 2.5 with phosphoric acid was prepared and thereafter mixed with different amounts of acetonitrile. The different chromatograms obtained during these experiments are shown in Figure 7.

As Figure 7 clearly illustrates, acetonitrile strongly affects retention of the investigated compound. Although the resolution steadily decreases with increasing acetonitrile content, the *k'* value of the second eluting peak could be reduced by a factor of 38 with a full baseline resolution of the enantiomers as a result.

Because the elution power of acetonitrile is significantly higher than for methanol, we generally prefer to start new experiments with a methanol–water–tailing reducer mixture. If the compounds of interest are too strongly retained with this eluent, methanol is systematically replaced by acetonitrile until an acceptable compromise between the retention factor and the resolution value is found.

pH In the analysis of ionizable compounds, pH can certainly have a strong effect on the chromatographic behaviour. We therefore investigated for the product series summarized in Table 2 the effect of pH variations in the range between 2.5 and 4.5 on a Chiralcel OJ-R using a mobile phase composed of methanol–acetonitrile and a 50 mmol L⁻¹ triethylamine solution in water adjusted to the desired pH value with phosphoric acid. For one of the products investigated, the different chromatograms obtained during these experiments are depicted in Figure 8.

Figure 8 shows that the retention factors steadily increase with increasing pH value, reaching

Figure 6 Effect of the anionic part of the tailing reducer on the resolution. Column: 250×4.6 mm i.d. Chiralcel OJ-R (*p*-methylbenzoyl cellulose). Flow rate: 1 mL min^{-1} . Mobile phase: 50 mmol L^{-1} triethylamine adjusted to a pH value of 2.5 with different acids-methanol (30 : 70; v/v).

maximum at pH 4 and decreasing again above this pH value. A similar pattern was also observed for the resolution value.

The different experiments that have been performed clearly indicate that, for ionizable compounds, pH can have an important effect on the enantioselectivity, which of course makes it a parameter to be investigated thoroughly during method development and optimization.

Chemically Bonded Polysaccharide Phases

Over the last few years, various attempts have been made to graft derivatized polysaccharides on to a silica matrix, without losing the chiral recognition properties of these materials. One of the major problems encountered was the limited amount of polysaccharide that could be chemically bonded. For the time being, only the French company Chiralsep (La Fresnaye) has a few chemically bonded polysacchar-

ide-based columns (Chirose-bond C1 and Chirose-bond C3) on the market.

We were able to test a few experimental chemically bonded polysaccharide phases. At first we compared a chemically bonded *p*-methylbenzoyl cellulose column with the corresponding physically coated material (Chiralcel OJ) using the classical alcohol-based mobile phases. Whereas on the coated phases most of the investigated compounds were partially or completely resolved with pure ethanol as the eluent, this was not the case on the chemically bonded material. For most of the compounds investigated it was necessary to dilute ethanol with *n*-hexane to obtain an acceptable resolution value. The experiments performed certainly prove that the chiral properties of the derivatized polysaccharide were not lost during the grafting process. However, compared to the coated phases, smaller retention factors were measured on the chemically bonded material. This is

Figure 7 Effect of type of polar modifier on chromatographic behaviour. Column: 250 × 4.6 mm i.d. Chiralcel OJ-R (*p*-methylbenzoyl cellulose). Flow rate: 1 mL min⁻¹. Mobile phase: 50 mmol L⁻¹ triethylamine adjusted to a pH value of 2.5 with phosphoric acid-methanol (30 : 70; v/v) + acetonitrile in different ratios.

possibly an indication that only a small quantity of the chiral moiety was chemically bonded on to the silica matrix. Also, some differences in enantioselective properties could be observed between both phases. Phenoperidine, for example, was not resolved with pure ethanol on the coated phase while on the chemically bonded column this product was very well separated, as illustrated in **Figure 9**.

A few experiments under reversed-phase conditions were also performed on the chemically bonded *p*-methylbenzoyl cellulose column. Methanol or ethanol in combination with a 0.5% ammonium acetate solution in water was used as the mobile phase.

For all the investigated compounds, the smallest retention and selectivity values were measured for ethanol as the organic modifier. For some products, extreme differences in resolution could be observed between the different experimental conditions applied. For an amino alcohol, the chromatograms obtained using methanol and ethanol as organic modifier are graphically compared in **Figure 10**.

Although only a limited number of experiments were performed, we can conclude that the tested chemically bonded polysaccharide phase has a high potential for reversed-phase applications.

Figure 8 Effect of pH variations on the chromatographic behaviour. Column: 250×4.6 mm i.d. Chiralcal OJ-R (*p*-methylbenzoyl cellulose). Flow rate: 1 mL min^{-1} . Mobile phase: 50 mmol L^{-1} TEA adjusted to the indicated pH values with phosphoric acid-methanol-acetonitrile (30 : 40 : 30; v/v).

Besides these experiments, a series of 37 racemates belonging to different product classes were investigated on chemically bonded equivalents of respective-

ly Chiralcel OJ, Chiralcel OD, Chiralpak AD and Chiralpak AS originating from a different source to the column used in the foregoing experiments.

For the first tests, pure ethanol was used as the mobile phase. Using this eluent, the largest number of products were separated on the chemically bonded equivalent of Chiralcel OJ. Twenty compounds were partially or completely resolved on this column, compared to six products on the cellulose 3,5-dimethylphenyl carbamate column, 14 products on the amylose 3,5-dimethylphenyl carbamate column and eight compounds on the chemically bonded equivalent of Chiralpak AS. However, the number of products that were separated on the chemically bonded *p*-methylbenzoyl cellulose column was only 69% of the number of products resolved on the physically coated Chiralcel OJ column, using the same eluent. Because for the same eluent composition similar retention factors were measured on the chemically bonded columns and their physically coated equivalents, we may conclude that the amount of cellulose or amylose grafted on to the silica matrix has to be the same order of magnitude as the amount present on the physically coated phases.

Other solvents were also used on these columns. After extensive use of dichloromethane, which normally dissolves cellulose and amylose derivatives, the properties of the columns were tested again and compared with the results obtained on a fresh column. Practically no difference in retention or resolution

Figure 9 Separation of phenoperidine. Column: 250×4.6 mm i.d. chemically bonded *p*-methyl benzoyl cellulose. Flow rate: 1 mL min^{-1} . Mobile phase: ethanol.

Figure 10 Separation of an amino alcohol under reversed-phase conditions. Column: 250 × 4.6 mm i.d. chemically bonded *p*-methylbenzoyl cellulose. Flow rate: 1 mL min⁻¹. Mobile phase: continuous line, 0.5% ammonium acetate in HPLC-grade water-ethanol (50 : 50; v/v); dotted line, 0.5% ammonium acetate in HPLC-grade water-methanol (50 : 50; v/v).

values could be observed before and after the use of dichloromethane. This is an indication that the polysaccharide derivative was perfectly bonded on to the silica matrix.

Some of our products were also investigated under normal-phase conditions on the Chirose-bond C1 column of Chiralsep. Most compounds eluted as relatively broad peaks with a severe tailing. From the 22 investigated compounds, only three products were fully baseline-resolved. The addition of a small amount of triethylamine did not solve the tailing problem. For only one of the investigated compounds was a very good resolution observed on the Chirose-bond C1. The results of these experiments are summarized in **Table 3**.

The ability to use dichloromethane for this compound is interesting for preparative chromatographic purposes, because the solubility of this product in the commonly used solvents (alcohol, or alcohol-*n*-hexane mixtures) is rather poor.

Some of the chemically bonded polysaccharide phases which have been tested certainly have a high potential. The possibility of using a broader pallet of solvents or solvent combinations especially widens for preparative chromatographic work the field of application.

Conclusions

Different types of derivatized cellulose and amylose stationary phases are nowadays commercially available. With a limited number of these phases it is possible to separate a broad variety of products. Furthermore, these phases are also extremely useful for preparative chromatographic applications.

Although differences in chromatographic behaviour between the tested chemically bonded phases and their physically coated equivalents have been observed, we might expect that, after further optimization of the grafting process, these phases will certainly enlarge the field of application of the derivatized cellulose and amylose materials.

Introduction

The Importance of Enantiomeric Separations

The separation of enantiomers of chiral compounds by chromatographic methods and related techniques is one of the important tasks in modern analytical chemistry, especially in the analysis of compounds of biological and pharmaceutical interest. However, analysis of this kind is also required in food analysis and the analysis of pesticides, flavours and fragrances. The reasons for this are as follows:

- As a consequence of the existing or potential differences between the biological–pharmacological activities of the antipodes of racemic drugs, analytical methods are required for their simultaneous determination in biological samples, thus enabling one to follow the fate of the enantiomers of the administered drug (candidate) in the animal or human organism.
- Asymmetrical syntheses are in the focus of interest in various fields of organic chemistry especially in the synthesis of drugs administered as the pure enantiomer. In these cases and also if the preparation of the enantiomers is carried out by classical resolution techniques, analytical methods are necessary for the determination of their enantiomeric purity.

Possibilities for Enantiomeric Separations

Since in achiral environment the physicochemical properties of the antipodes of racemates are identical, their separation is not possible if the generally used, achiral separation systems – ordinary high-perfor-

mance liquid chromatography (HPLC) and gas chromatography (GC) columns, thin-layer chromatography (TLC) plates, capillary electrophoresis (CE) capillaries, etc., with ordinary mobile phases – are used. The main possibilities for the separation of enantiomers are:

- Transformation of the enantiomers to covalently bonded diastereomeric derivatives by reacting them with homochiral derivatizing reagents prior to their chromatographic separation using achiral stationary phases or and mobile phases. The detailed description of this general method, which is often referred to as an indirect method, is described here.
- Incorporation of the chiral reagent in the mobile phase for the dynamic formation of diastereomeric adducts, ion pairs or complexes with the enantiomers to be separated during the chromatographic run. In this case also, achiral stationary phases are used.
- Separation of the enantiomers on chiral stationary phases (HPLC, GC and TLC). Although in principle this general method does not require derivatization, the separation can be improved in many cases by modifying the enantiomers using pre-column achiral derivatization. These aspects are also briefly discussed here.

Covalent Chiral Derivatization of Enantiomers and Separation of the Diastereomeric Derivatives on Achiral Columns

Introductory Remarks: the Role of Covalent Chiral Derivatization in Enantiomeric Separations

The derivatization of enantiomers using homochiral reagents to form their diastereomeric derivatives

separable on achiral GC or HPLC columns or TLC plates was the first, widely used general method in the chiral analysis of drugs and related materials. After the introduction of newer chromatographic and capillary electrophoretic techniques briefly mentioned above, the importance of enantioseparations based on covalent chiral derivatization has naturally decreased to some extent. However, this general method is still a method of choice widely used especially in HPLC. The reasons for this are the large number of commercially available homochiral reagents and well-established reactions enabling diastereomeric derivatives with excellent separation and detection possibilities to be formed and the possibility of tailor-made separations using inexpensive, achiral columns, i.e. being in possession of the *R*- and *S*-forms of the reagent, it is possible to have the peak of the enantiomeric impurity eluting before the main peak.

The importance of covalent chiral derivatization can be characterized by the large number of publications (above 300) from the early 1970s up to the present time. References to the most important publications from this field can be found in chapters in books and review papers listed in Further Reading which cover the literature until 1993. The relatively large number of papers published after 1993 describing new applications of previously described derivatization reagents, moreover the introduction of new reagents is an indication that this branch of chiral analysis has retained some of its importance to the present day (see figure legends).

Important Features of Chiral Derivatization Reactions and Reagents

The presence of a suitable functional group in the molecule of the analyte The prerequisite of the use of any kind of enantioseparation based on covalent, chiral derivatization is the presence of at least one functional group (amino, hydroxyl, carboxyl, epoxy, thiol, etc.) in the molecule of the chiral compound which is capable of reaction with the reactive group of the derivatizing reagent.

Good chromatographic properties of the derivatives The optimization of the chromatographic parameters of retention time, peak shape and separability of the enantiomers from other components of the complex mixture by proper selection of the column (usually reversed-phase but in some cases normal phase columns), and the composition and pH of the eluent is done in the usual ways for achiral HPLC.

Sufficient separation of the diastereomers formed This is also influenced by the above-mentioned sol-

vent composition and column selection, but in this case it is even more important to select a proper derivatizing reagent enabling diastereomers to be formed with sufficiently different molecular fine structures for their chromatographic separation. If the number of the chiral centres in the analyte is more than one, the reagent should enable the separation of all stereoisomers. An example for this is the separation of (*S,R*), (*R,S*), (*S,S*) and (*R,R*) nadolol in **Figure 1**.

The structural features which influence the separation of the diastereomers are:

- The distance between the two chiral centres. In the majority of cases this is two to four atoms but there are many exceptions to this rule.
- Conformational rigidity of the diastereomers favours resolution. Bulky groups in the vicinity of one of the chiral centres or the incorporation of one of them into a ring system are especially advantageous. For example, in the case of one of the most widely used chiral derivatizing reagent, GTC (2,3,4,6-tetra-*O*-acetyl- β -D-glucopyrasonyl isothiocyanate, see later) the chiral centres of the reagent are in the pyrane ring. The exchange of the acetyl groups to the bulkier benzoyl groups improves the resolution. The position and bulkiness of the remote functional groups also influences the separation of the diastereomers. In these instances, however, the direction of the influence is difficult to predict. As an example, the investigation leading to the highly efficient derivatizing agent for the amino group (+)-2-methyl-2 β -naphthyl-1,3-benzodioxole-4-carboxylic acid chloride is mentioned. It was found that the difference between the bulkiness of the two substituents at C-2 favourably influences the separation and with the isomeric 5-carboxylic acids only poor separation is achievable.
- The formation of hydrogen bonds. For example, in the case of propranolol the secondary amino group of the molecule is transformed by chiral isocyanates or isothiocyanates to diastereomeric urea or thiourea derivatives. The formation of a hydrogen bond between the carbonyl or thiocarbonyl group of the latter and the free hydroxyl group of propranolol plays an important role in the separation: the resolution deteriorates with etherification of the hydroxyl group.

Selection of the elution order This is especially important if the aim of the analysis is the determination of trace level enantiomeric impurity in a drug which is administered as the pure enantiomer. In order to have the impurity peak appear before the main peak the

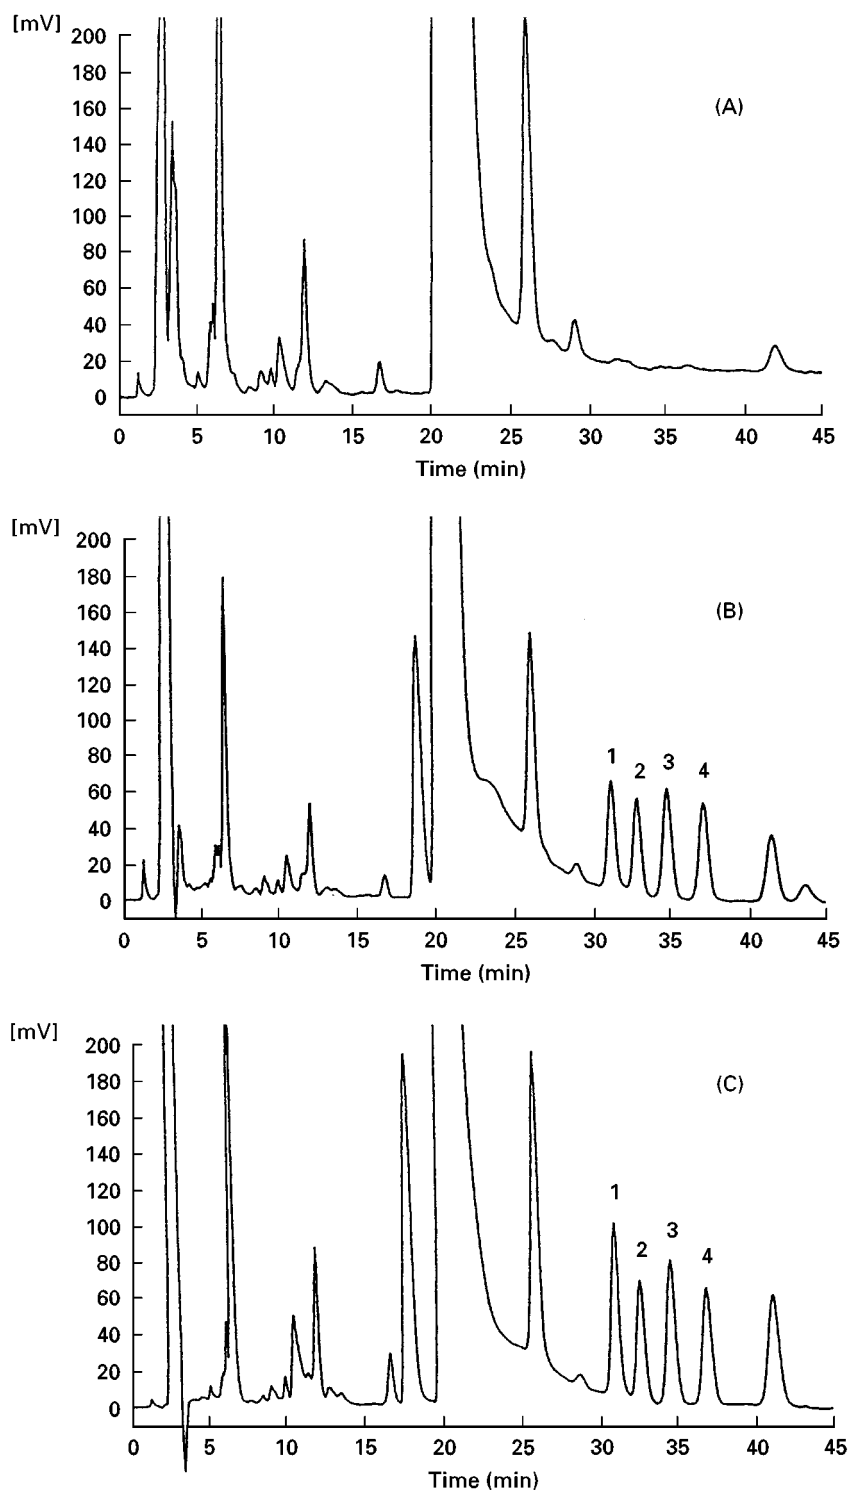

Figure 1 Resolution of the four diastereomers of the two racemates of nadolol as urea derivatives after reaction with (*R*)-(–)-1-(naphthyl)ethyl isocyanate and their determination in dog plasma extracts. Column YMC-AM-303 ODS(250 × 4.6 mm, 5- μ m); mobile phase, water–acetonitrile (60:40, v/v); flow rate, 1 mL min⁻¹; temperature, 40°C; UV detection at 285 nm. (A) Blank control dog plasma; (B) plasma spiked with 50 ng ml⁻¹ of each diastereomer; (C) plasma obtained 2 h after oral administration of 1 mg kg⁻¹ of racemic nadolol. Peaks: 1, (*S,R*)-nadolol; 2, (*R,S*)-nadolol; 3, (*R,R*)-nadolol; 4 (*S,S*)-nadolol. Reproduced with permission from Hoshino M, Yajima K, Suzuki Y and Okahira A (1994) *Journal of Chromatography B* 661: 281, copyright Elsevier.

proper chromatographic system (normal- or reversed-phase) has to be selected; it is even more advantageous to select a derivatizing agent that is available in both the *R* and *S* forms. Curves a and b in Figure 2 demonstrate this: the elution order of amino acids changes upon changing from *R* to *S* reagent in their derivatization with the *o*-phthalaldehyde-*N*-butyryl-cysteine reagent.

Unidirectional derivatization reaction taking place under mild conditions The most widely used reactions are completed at room temperature within 1 h and the reaction mixture can be injected directly into the chromatograph. The necessity of heating or extraction of the reaction mixture does not preclude a reaction being used and nor does the occurrence of side reactions, provided that their products do not interfere with the detection and quantification of the peaks of the main products and the side reactions do not show stereospecificity.

Enantiomeric purity and stability of the derivatizing reagent The enantiomeric purity of the reagent is one of the most important factors determining the success of the determination of the enantiomeric purity of the analyte. It is evident that when using a homochiral reagent containing its antipode as an impurity, the latter also reacts with the main component of the analyte. This results in a diastereomeric derivative which has the same retention time as that originating from the reaction of the main component of the reagent and the impurity of the analyte. It is therefore difficult to estimate if the satellite peak originates from the impurity of the reagent or from that of the analyte. If the aim of the study is the determination of the enantiomeric purity of a drug administered as pure enantiomer and the test limit for the antipode is 0.5%, the enantiomeric purity of the reagent should be at least 99.9%. If the requirement for the enantiomeric purity of the drug is higher, the purity of the reagent should be even higher. If the aim is the determination of commensurable amounts of enantiomers (e.g. in biological samples), 1–2% of the enantiomeric impurity in the reagent is tolerable.

The enantiomeric purity of the reagent can be checked if the enantiomers of the analyte (or at least one of them) are available in enantiomerically pure form. The relative peak area of the diastereomeric impurity after the reaction with the reagent will be characteristic of enantiomeric impurity of the reagent.

The enantiomeric stability of the reagent is also an important prerequisite to obtain reliable results. For

example, *N*-trifluoroacetyl-(*S*)-(–)-prolyl chloride or anhydride, were found to racemize upon storage. Reagents which are available commercially at the present time fulfil this requirement.

The absence of kinetic resolution and racemization The absence of kinetic resolution, e.g. difference between the reaction rates of the two enantiomers with the reagent and the enantiomeric stability of the analyte and its diastereomeric derivative are important prerequisites of the applicability of a reagent to a given purpose. These can be checked by comparing the peak areas of the diastereomers during and after the reaction with a racemate. The peak area should be close to unity.

Good chromophoric or fluorophoric properties of the reagent Although the primary aim of derivatization in chiral chromatography is the formation of easy to separate diastereomeric derivatives it is advantageous if, at the same time, the reagent improves the detectability of the separated enantiomers by introducing chromophoric or fluorophoric groups into their molecules. A typical example for such 'dual-purpose' fluorophoric reagents is (–)-2-[4-(1-aminoethyl)phenyl]-6-methoxybenzoxazole. The detection limit for the enantiomers of 2-phenylpropionic acid after derivatization with this reagent is as low as 10 fmol (1.5 pg). Many more examples of this type are presented in the next section.

It is important to note that the UV or fluorescence characteristics of the diastereomers formed are not necessarily equal and therefore have to be checked during the validation of a new method by comparing the spectra and band intensities of the diastereomers.

Covalent Enantiomeric Derivatization of Some Important Functional Groups

Derivatization of amines The reagents suitable for the chiral derivatization of amines can be categorized as follows:

Activated carboxylic acids These are usually carboxylic chlorides and the reaction with primary and secondary amines leads to diastereomeric carboxamides. The classical reagent *R*(+)- α -methoxy- α -(trifluoromethyl)phenylacetyl chloride is still in use for the preparation of gas chromatographically separable diastereomers. Some others ('dual-purpose' reagents with strong UV absorption or fluorescence) include 1-(4-nitrophenylsulfonyl)-*L*-prolyl chloride, dansyl-*L*-proline activated by triethylamine/diethyl phos-

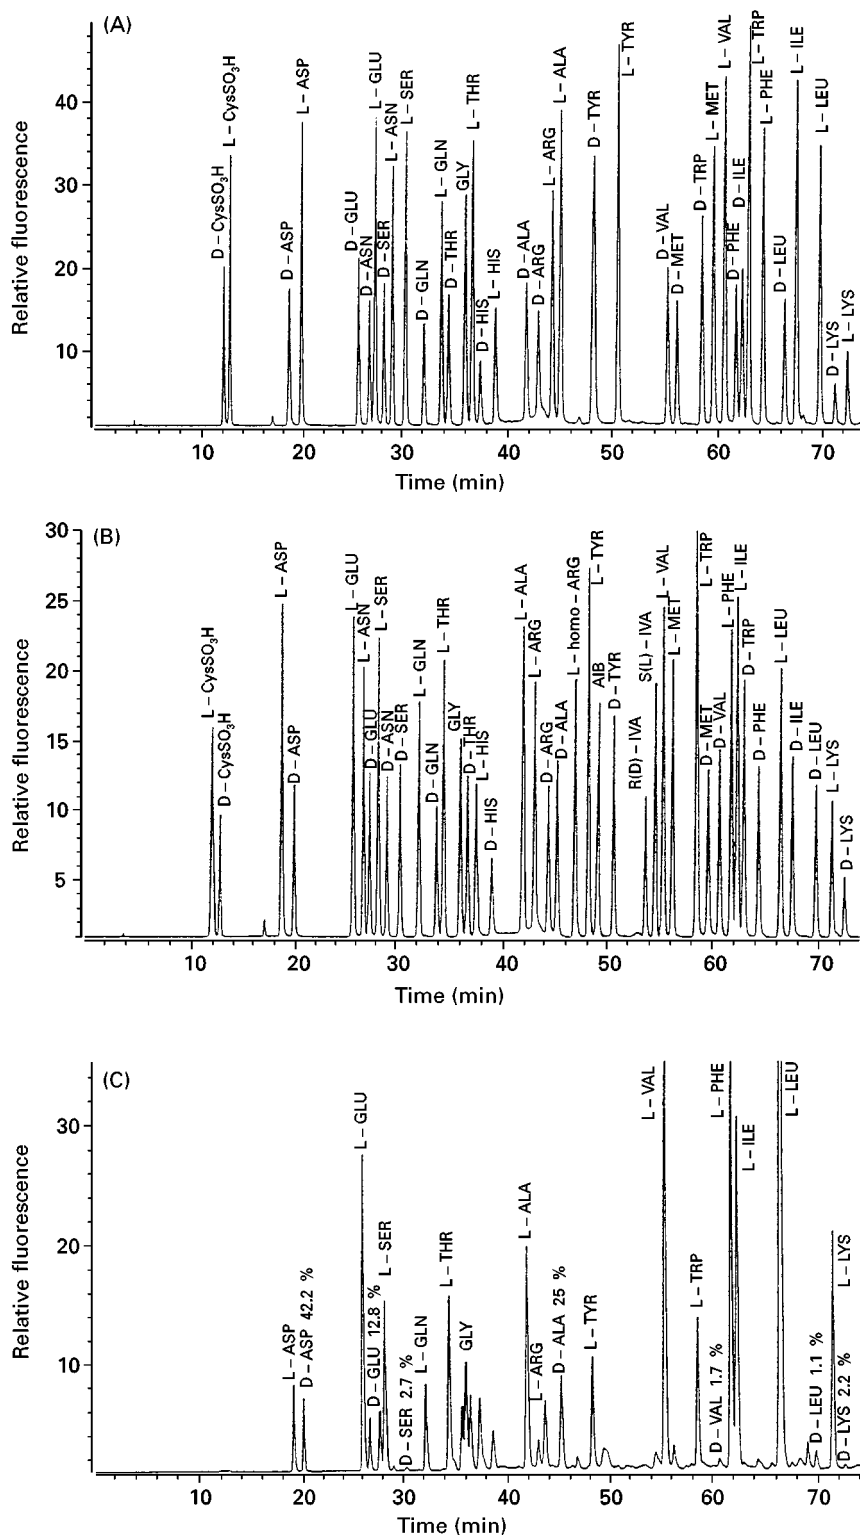

Figure 2 High-performance liquid chromatographic (HPLC) elution profile of the mixture of L and D-amino acids (L : D = 2 : 1), glycine and L-homo-arginine (internal standard) derivatized as the isoindoles with (A) *o*-phthalaldehyde-*N*-isobutryl-D-cysteine and (B) *o*-phthalaldehyde-*N*-isobutryl-L-cysteine; (C) amino acids from an ethanolic extract of *Lactobacillus acidophilus*, derivatization with *o*-phthalaldehyde-*N*-isobutryl-L-cysteine. Column, Hypersil ODS (250 × 4 mm, 5 μm); mobile phase, gradient elution; A = 23 mM sodium acetate (pH 5.95); B = methanol-acetonitrile (600 : 50 v/v), linear gradient from 0% B to 53.5% B in 75 min; flow rate 1 mL min⁻¹; fluorescence detection, 230 nm excitation, 445 nm emission. phorocyanidate, *N*-[4-(6-methoxy-2-benzoxazolyl)] benzoyl-L-phenylalanine or -proline, activated by 2,2'-dipyridyl disulfide/triethylphosphine, *N*-benzyloxycarbonyl-L-phenylalanine, activated by acetic anhydride(+) -2-methyl-2 β -naphthyl-1,3-benzodioxole-4-carboxylic acid chloride, (*S*)-(+) -naproxen chloride, (*S*)-(+) -flunoxaprofen chloride, (*S*)-(+) -benoxaprofen chloride, etc. Their strong fluorescence enables the enantiomers of chiral drugs such as tranilcypromine, tocainide, carvedilol, baclofen and propranolol to be determined. (The isocyanate, isothiocyanate and chloroformate derivative of these compounds have also been introduced as chiral derivatizing agents as shown in the subsequent sections.)

An on-line solid-phase derivatization reagent is fluorenylmethyloxycarbonyl-L-proline (Fmoc-L-proline), bonded to beads of a styrene-divinylbenzene copolymer as the active ester of a 4-hydroxy-3-nitrobenzophenone moiety. By positioning the HPLC column after the reaction column, the transformation of chiral amines (e.g. amphetamine) to their highly fluorescent diastereomeric Fmoc-L-prolyl derivatives and their separation was achieved.

formate is that it is suitable for the derivatization of the tertiary amine promethazine via demethylation of the dimethylamino moiety.

Isocyanates These reagents form diastereomeric urea derivatives with chiral primary and secondary amines. (*R*)-(-)- and (*S*)-(+)-1-(1-naphthyl)ethyl isocyanate and (*R*)- α -methylbenzyl isocyanate are among the classical chiral derivatizing reagents. Isocyanate derivatives of the drugs mentioned in one of the previous sections as the carboxylic chlorides and (*R*)-*N*-3,5-dinitrobenzoyl)phenyl glycine have also been used for the derivatization of β -blockers and other amines. Eqn [1] shows the reaction between nadolol and (*R*)-(-)-1-(1-naphthyl)ethyl isocyanate, while the separation of the four diastereomers of the two racemates is depicted in Figure 1. It is remarkable that by selecting a suitable reagent and proper chromatographic conditions not only can the four diastereomers be separated but the interference from dog plasma can also be eliminated.

Chloroformates The above-mentioned Fmoc group has been incorporated into another types of chiral reagents: (+)-1-(9-fluorenyl)ethyl chloroformate is one of the most widely used derivatization reagents for the chiral HPLC of amino acids, β -blockers, to form the corresponding carbamate derivatives.

An interesting feature of another widely used reagent of the chloroformate type, (-)-menthyl chloro-

Isothiocyanates Of the isothiocyanates forming thiourea derivatives with primary and secondary amines, GITC is most widely used. If the four acetyl groups are replaced by benzoyl groups the sensitivity of the detection is greatly improved. Other reagents of this type leading to highly fluorescent derivatives include (*R*)-(-)- and (*S*)-(+)-4-(3-isothiocyanatopyrrolidin-1-yl)-7-nitro-2,1,3-benzoxadiazole and its 7-(*N,N*-dimethylaminosulfonyl) analogue as well as DDITC ((1*R*,2*R*)- and (1*S*,2*S*)-*N*-[(2-isothio-

cyanato)cyclohexyl]-3,5-dinitrobenzoylamide, which excels with the high chemical stability, high UV activity and the excellent separability of the diastereomeric derivatives. The equation of the reaction of GITC and DDITC with the β -blocker metoprolol and the separation of the derivatives are depicted in eqn [2] and Figure 3, respectively.

N-Haloarylamino acid derivatives Marfey's reagent (1-fluoro-2,4-dinitrophenyl-5-L-alaninamide) is one of the most generally used reagents in the analytical control of racemization during peptide synthesis. The peptides are split either by hydrochloric acid or enzymatically. The nucleophilic attack of the α -amino group of the amino acids on the C-F bond activated by the two nitro groups on the aromatic ring results in a smooth reaction to form diastereomeric aniline derivatives with good UV detectability (see eqn [4]). The

valinamide analogue of the Marfey reagent gives even better resolution.

***o*-Phthalaldehyde + chiral thiols** This dual derivatization reaction leading to fluorimetrically highly active isoindole derivatives is another generally used method in the chiral analysis of amino acids (see eqn

[3]). As the chiral thiol *N*-acetyl-L-cysteine is most widely used but the use of 2,3,4,6-tetra-*O*-acetyl-1-thio- β -D-glucopyranoside and *N*-isobutyryl-L-cysteine (and D-cysteine) have been found to be advantageous in the resolution of the diastereomers. The reaction of amino acids with *o*-phthalaldehyde and the latter reagent is shown in eqn [3], while in Figure 1 the separation of as many as 36 enantiomers of 18 amino acids and amino acid analogues as well as glycine is depicted together with a practical application.

Enzymatic deamination Chiral HPLC of a mixture of amino acid enantiomers with and without selective oxidative deamination of D-amino acids with the aid of the enzymes D-amino acid oxidase and catalase enables D-amino acids to be identified in the mixture.

Derivatization of the carboxyl group

Esterification with chiral alcohols (+)- or (-)-2-octanol, (+)-1-phenylethanol, (-)-menthol, (+)- or (-)-2-butanol are the classical reagents for the chiral analysis of carboxylic acids. The reactions usually require harsh conditions and for this reason the danger of racemization should be taken into consideration.

Amidation with chiral amines Prior to their reactions with chiral amines the carboxyl group should

UV or fluorometric properties are also in use, e.g. (*R*)- α -methyl-4-nitrobenzylamine, (*R*)-(+)-1-(1-naphthyl)ethylamine, (-)-1-(1-anthryl)ethylamine, *R*-(-)- and (*S*)-(+)-amphetamine, (1*R*,2*R*)-(-)- or (1*S*,2*S*)-(+)-2-amino-(4-nitrophenyl)-1,3-propanediol, L-leucinamide, L-alanine- β -naphthylamide, L- or D-O-(4-nitrobenzyl)tyrosine methyl ester, (-)-2-[4-(1-aminoethyl)-phenyl]-6-methoxybenzoxazole and other related derivatives where the 1-aminoethyl group is replaced by L-leucyl or D-phenylglycyl groups, drug-related amines (flunoxaprofen amine, benoxaprofen amine and naproxen amine), (*R*)- and (*S*)-1-(4-dansylaminophenyl)ethylamine, etc. The reaction of ibuprofen and pranoprofen with the last reagent and the separation of the diastereomeric carboxamide derivatives are shown in eqn [4] and Figure 4, respectively.

be activated. Possibilities for this are, e.g. reaction with thionyl chloride to form carboxylic chlorides, with chloroformates to form mixed anhydrides, with 1,1-carbonyldiimidazole to form reactive *N*-acylimidazoles and with the classical coupling agent dicyclohexylcarbodiimide to form the reactive *N*-acylurea derivatives. The classical but still widely used amine reagent is (*S*)-(-)- α -methylbenzylamine, but several others with excellent separation power,

Derivatization of the alcoholic and phenolic hydroxyl groups The most frequently used general method for the derivatization of the hydroxyl group of chiral alcohols and phenols is esterification. A great variety of chiral carboxylic acids have been used for this purpose such as *R*(+)- and *S*(-)- α -methoxy- α -(trifluoromethyl) phenylacetic acid (Mosher's acid), *R*(+)-*trans*-chrysanthemic acid, (-)-menthenyloxyacetic acid for the gas chromatographic or HPLC

Figure 3 Resolution of (*R,S*)-metoprolol derivatized as (*R,R*)-DDITC- and GITC-thioureas. Column, Hypersil ODS (125 × 4 mm, 5 μm); mobile phase, acetonitrile-20 mM ammonium acetate 55:45, v/v; flow rate 1 mL min⁻¹ detection at 254 nm. separation with UV detection and (–)-(1*S*,2*R*,4*R*)-*endo*-1,4, 6,7,7-hexachlorobicyclo[2.2.1]-hept-5-ene-2-carboxylic acid and (*S*)-(+)-2-*tert*-butyl-2-methyl-1,3-benzodioxolo-4-carboxylic acid for HPLC separation with fluorimetric detection, etc. Dicyclohexylcarbodiimide can be used as the coupling agent, but the use of *in situ* transformation of the acids to their chlorides by the addition of thionyl chloride is more widespread. The direct enzymatic D-(+)-glucuronidation reaction of phenols has also been described.

Acyl chlorides, anhydrides and acyl cyanides can be used directly. For example (–)-camphanic acid, *R*(+)- α -methoxy- α -(trifluoromethyl)phenylacetyl chloride, β -naphthylsulfonyl-L-prolyl chloride, flunoxaprofen chloride, (*R,R*)-*O,O*-diacetyl- (or di-*p*-toluoyl-) tartaric anhydride and (–)-2-methyl (or methoxy)-1,1'-binaphthalene-2'-carbonyl cyanide lead to well-separable, UV or fluorimetrically active diastereomeric ester derivatives with chiral alcohols.

As an illustration, the reaction of delmopinol and its analogue used as the internal standard in the determination of the drug in plasma with the reagent (*R,R*)-*O,O*-di-*p*-toluoyl-tartaric anhydride is shown in eqn [5]. The separation is depicted in Figure 5.

Figure 4 Resolution of (A) (*R,S*)-ibuprofen and (B) (*R,S*)-pranoprofen as the carboxamides formed with (*S*)-1-(4-dansylaminophenyl)ethylamine. Column ODS-80TM (150 × 4.6 mm, 5 μm); mobile phase: 50 mM sodium acetate (pH 6.5)-acetonitrile (A) 30:70, v/v and (B) 45:55, v/v, and flow rate 1 mL min⁻¹; fluorescence detection, 338 nm excitation, 535 nm emission. Reproduced with permission from Iwaki K, Bunrin T, Kameda Y and Yamazaki M (1994) *Journal of Chromatography A* 662: 87, copyright Elsevier.

Further derivatization reactions include the use of (*R*)-1-(1-naphthyl)ethyl isocyanate for the derivatization of, e.g. diacylglycerol derivatives to form the corresponding carbamates. The lower reactivity of the hydroxyl group compared with the

amino group can be overcome by using a suitable catalyst (4-pyrrolidinopyridine). (–)-Menthyl chloroformate, which has already been mentioned, has also found application here as a reagent for amines; the reaction products with chiral alcohols are carbonates.

Figure 5 Resolution of (–)- and (+)-delmopinol (peaks 1 and 2) and (–)- and (+)-internal standard (peaks 3 and 4) and their determination in human plasma extracts. Derivatization of the aldehyde group The importance of this kind of chiral derivatization reactions is much smaller than those described for amines, carboxylic acids and alcohols. For example, aldoses can be transformed with L-cysteine methyl ester to diastereomeric thiazolidine derivatives which can be separated by GC after trimethylsilylation. The two aldehyde groups of gossypol were transformed with (*R*)-(-)-2-amino-1-propanol to the diastereomeric Schiff's bases separable by HPLC.

Derivatization of epoxides The oxirane ring of chiral epoxides is opened by sodium sulfide to form a vicinal hydroxythiol derivative. In the second step of the derivatization reaction the thiol group reacts with *o*-phthalaldehyde and a chiral amino acid to form the diastereomeric isoindole derivative mentioned in the section dealing with the derivatization of the amino group. Another ring-opening reagent is 2-propylamine. The secondary amino group of the 1,2-amino alcohol is then reacted with 2,3,4,6-tetra-*O*-acetyl (or benzoyl)- β -D-glucopyranosyl isothiocyanate to form the diastereomeric thiourea derivatives.

Derivatization of the thiol group The formation of diastereomeric isoindole derivatives from chiral amino acids, chiral thiols and *o*-phthalaldehyde (already mentioned in the section dealing with the derivatization of the amino group; see eqn [4]) can also be used for the enantioseparation of thiols. Reagents of other types are (*R,R*)-dinitrobenzoyldiaminocyclohexyl isothiocyanate and *N*-[(2-isothiocyanato)cyclohexyl]-pivalinoyl amide which transform the thiol compound to their diastereomeric dithiocarbamate derivatives.

Derivatization of Enantiomers With Achiral Reagents to Improve Their Chromatographic Properties and Their Separation on Chiral Columns

Introductory Remarks

Chiral columns enable the direct separation of enantiomers. In many cases the chromatographic properties of the enantiomers can be improved by transforming them to suitable derivatives using achiral reagents.

Pirkle-Type Chiral Columns

The purposes of using pre-column derivatization are:

- Blocking of the polar groups of the analyte (amino, carboxyl, hydroxyl groups) to avoid strong interactions with the polar groups of the chiral selector thus improving the separation.
- The introduction of aromatic rings into the analyte to enable π - π interactions to take place between the aromatic moieties of the chiral selector and the analyte which play a dominant role in the resolution of the enantiomers.
- Improve UV detectability.

To fulfil these requirements amino groups in the analyte are usually transformed to aromatic acyl derivatives by 4-nitro- or 3,5-dinitrobenzoyl chloride or to aromatic urea or thiourea derivatives by means of phenyl-, 4-fluorophenyl-, 4-methoxyphenyl-, 3,5-dinitrophenyl- or 1-naphthyl-isocyanates and isothiocyanates. Carboxyl derivatives are derivatized after activation with thionyl chloride or carbodiimides to form anilides, 3,5-dimethylanilides, 3,5-dinitroanilides, naphthylmethanilides, etc. The derivatizing agents for the hydroxyl group are benzoyl chloride, 3,5-dinitrobenzoyl chloride, 1-naphthyl chloride to form ester derivatives and 1-naphthyl- or 3,5-dinitrophenyl isocyanates to form the corresponding carbamates.

Cyclodextrin-Bonded Phases

In the case of enantiomeric HPLC separations on cyclodextrin-bonded stationary phases the necessity of pre-column achiral derivatization is not as general as with the Pirkle-type phases. The introduction of the aromatic ring into analytes often improves their separation. Amino acids are usually derivatized with dansyl chloride, 3,4-dinitrobenzoyl chloride, *o*-phthalaldehyde/2-mercaptoethanol, etc., or with highly fluorescent reagents such as 9-fluorenylmethyl chloroformate, 9-fluorenylmethoxycarbonylglycine chloride, 6-aminoquinolyl-*N*-hydroxysuccinimidyl carbamate, etc.

α_1 -Acid Glycoprotein Column

In most instances no derivatization is necessary to obtain good enantioseparation. In the case of carboxylic acids, separation is improved by the addition of ion pairing agents to the eluent. For some basic drugs anionic reagents in the eluent also improves the column efficiency, peak symmetry and resolution.

Covalent derivatization is only seldom used. Acetylation or formylation of the amino and hydroxyl groups, esterification of the carboxyl group

with 2-propanol have been found in some instances to improve the separation.

Functionalized Cellulose Phases

In the overwhelming majority of cases enantiomers can be separated on these columns without derivatization. In a few instances esterification of the carboxyl group and the introduction of a benzoyl group into the molecule have been found advantageous.

Conclusions and Future Trends

It is indisputable that the direct chromatographic enantioseparations based on chiral stationary phases has greatly surpassed the importance of indirect separations based on covalent chiral derivatization. The fact that the overwhelming majority of papers reporting on the development and application of chiral separations are from these fields does not necessarily reflect the real of the contribution of covalent chiral derivatization in the solution of practical problems in pharmaceutical and biomedical analysis. In some areas (e.g. the determination of small concentrations of D-amino acids in various biological samples, etc.) the well-established classical methods are still in use. It is also remarkable that the combination of chiral derivatization with the use of chiral stationary phases has proved to be suitable for the solution of very delicate problems (separation of several enantiomers and diastereomers of drugs with more than one chiral centre). It should also be noted that the combination of chiral chromatography with fluorescence derivatization enables the limit of detection of enantiomeric impurities to be decreased to the 10 ppm. level. These tendencies are expected to continue in the near future.

Countercurrent Chromatography

Introduction

Countercurrent chromatography (CCC) is a generic term for support-free liquid/liquid partition chro-

matography, which can be used for the separation of a variety of enantiomers by dissolving a chiral selector (CS) in the liquid stationary phase. The method eliminates the time-consuming procedure which involves chemically bonding the chiral selector to a solid support for chiral chromatography. It also provides an important advantage over the conventional methods in that the same column can be used for the separation of various enantiomers simply by

dissolving the suitable chiral selector in the liquid stationary phase.

In the past various hydrostatic CCC systems, such as droplet CCC, rotation locular CCC (RLCCC) and centrifugal partition chromatography (CPC), have been used for the separation of chiral compounds. None of those techniques, however, is considered satisfactory for preparative purposes in terms of sample size, resolution and/or separation time. Recently, the hydrodynamic CCC system termed high speed CCC has remarkably improved the technique so that highly efficient separations can be achieved in a short elution time. This technique has been successfully applied to the separation of racemates using a Pirkle-type chiral selector. In this method analytical (milligram) and preparative (gram) separations can be performed simply by adjusting the amount of chiral selector in the liquid stationary phase in the standard separation column. Gram quantities of enantiomers can be obtained by pH-zone-refining CCC, a new preparative separation technique recently developed for the separation of ionizable compounds (see pH-zone-refining CCC). In addition, the present method allows computation of the formation constant of the chiral-selector complex, one of the most important parameters for studies on the mechanism of enantioselectivity.

Standard High speed CCC Technique for Chiral Separation

The separations are performed using a commercial high speed CCC centrifuge equipped with a set of multilayer coil separation columns. The two-phase solvent system is selected in such a way that the target

analyte has a partition coefficient ranging from 0.5 to 1 in the CS-free solvent system. When the organic phase is used as the stationary phase, the chiral selector may be made hydrophobic by attaching a long hydrocarbon chain to enhance both solubility and retention in the stationary phase.

In each separation, the column is first filled about half way with the CS-free stationary phase. This is followed by introduction of the CS-containing stationary phase (about 60% of the total column capacity) by discharging the excess amount of CS-free stationary phase from the other end of the column. In this way some amount of CS-free stationary phase (about 10% of the stationary phase retained in the column) remains at the end of the column during separation to absorb carried-over CS from the mobile phase which would contaminate the eluted fractions. After the sample solution is injected through the sample port, the mobile phase is pumped into the column while the column is rotated at the required speed, usually 800–1000 rpm. If desired separation can be carried out by successive injection of samples without replenishing the CS-containing stationary phase.

Figure 1 shows the separation of four pairs of dinitrobenzoyl (DNB)-amino acid enantiomers by the standard CCC technique using a two-phase solvent system composed of hexane/ethyl acetate/methanol/10 mM HCl with *N*-dodecanoyl-L-3,5-dimethylanilide as a CS in the organic stationary phase. Because of its high hydrophobicity ($K > 100$), this CS has high solubility in the organic stationary phase and is almost entirely partitioned into the stationary phase. All analytes were well resolved in 1–3 h. This chiral selector is similar to the 'Pirkle'

Figure 1 Separation of four racemic pairs of DNB-amino acids by the standard high speed CCC technique. Experimental conditions: apparatus: multilayer coil high speed CCC centrifuge with a semipreparative column of 1.6 mm i.d. and 330 mL capacity; solvent system: hexane/ethyl acetate/methanol 10 mM HCl (8 : 2 : 5 : 5, v/v/v/v), *N*-dodecanoyl-L-proline-3,5-dimethylanilide (CS) (2 g) was added to the organic stationary phase (200 mL) as a chiral selector; samples: from left to right, (±)-DNB-phenylglycine, (±)-DNB-phenylalanine, (±)-DNB-valine, and (±)-DNB-leucine, 5–10 mg of each dissolved in 5 mL of solvent consisting of equal volumes of each phase; flow rate: 3.3 mL min⁻¹; revolution: 800 rpm; analysis of fractions: optical rotation and circular dichroism; stationary phase retention: 65% of the total column capacity.

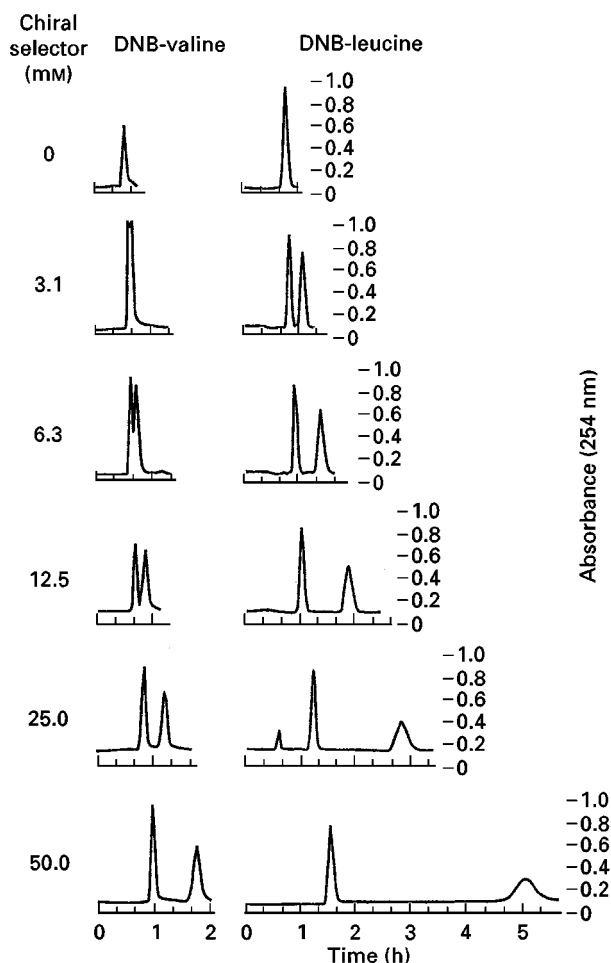

Figure 2 Effects of the amount or concentration of CS on the separation of DNB-amino acid racemates. In all resolved chromatograms, the first peak represents (–)-enantiomer and the second peak (+)-enantiomer. Experimental conditions: apparatus and column: see the Figure 1 caption; sample: racemic DNB-amino acid mixture consisting of DNB-valine and DNB-leucine, each 5–10 mg dissolved in 2 mL of solvent (1 mL of each phase); solvent system: hexane/ethyl acetate/methanol/10 mM HCl (8 : 2 : 5 : 5, v/v/v/v); stationary phase: upper organic phase with CS ranging from 0 to 4 g in 200 mL as indicated; mobile phase, lower aqueous phase; flow rate: 3 mL min^{–1}; revolution: 800 rpm.

chiral stationary phase which has been introduced for the HPLC separation of racemic DNB-amino acid *t*-butylamides. For CCC separation an *N*-dodecanoyl group was covalently attached to the CS molecule to increase its hydrophobicity so that it is almost entirely partitioned into the organic stationary phase.

The effect of the CS concentration in the stationary phase on the peak resolution was investigated by a series of experiments as shown in Figure 2. As the CS concentration was increased, the separation factor and peak resolution were increased as indicated by eqn [6]. The results clearly imply an important technical strategy for the present method: the best peak

resolution is attained by using a saturated solution of the CS in the stationary phase in a given column, and the resolution is further improved by using a longer and/or wider-bore coiled column which can hold a greater amount of CS in the stationary phase.

The preparative capability of the system was investigated on the separation of DNB-leucine enantiomers by varying the CS concentration in the stationary phase. The results shown in Figure 3 indicate that the sample loading capacity is mainly determined by the CS concentration in the stationary phase, i.e. the higher the CS concentration, the greater the peak resolution and sample loading capacity. As mentioned earlier, the standard HSCCC column (typically 300 mL in capacity) can be used for both analytical and preparative separation simply by adjusting the CS concentration in the stationary phase.

pH-Zone-refining CCC for Chiral Separation

pH-Zone-refining CCC is a powerful preparative technique that yields a succession of highly concentrated rectangular solute peaks with minimum overlap where impurities are concentrated at the peak boundaries. This technique has been applied to the resolution of DNB-amino acid racemates using a binary two-phase solvent system where the retainer acid and chiral selector were added to the organic stationary phase and the eluent base to the aqueous mobile phase. Figure 4 shows a typical chromatogram of a DNB-leucine racemate obtained by pH-zone-refining CCC. The pH of the fraction (dotted line) reveals that the peak is evenly divided into two pH zones with a sharp transition. Compared with the standard CCC technique, the pH-zone-refining CCC technique allows separation of large amounts of analyte in a shorter elution time.

Determination of Formation Constant of CS–Enantiomer Complex

The present technique has an advantage over conventional HPLC by allowing the determination of the formation constant (K_f) for the CS–enantiomer complex which is useful for developing the CS for chiral chromatography.

In a schematic view of the portion of the separation column in Figure 5, enantiomers (A_+ and A_-) are partitioned between the organic stationary phase (upper half) and the aqueous mobile phase (lower half). In the organic stationary phase enantiomers form a CS complex $[CSA_{\pm}]$ according to their formation constants ($K_{f\pm}$). In this situation:

$$D_{\pm} = ([A_{\pm}]_{\text{org}} + [CSA_{\pm}]_{\text{org}})/[A_{\pm}]_{\text{aq}} \quad [1]$$

Figure 3 Preparative separation of DNB-leucine racemate by high speed CCC. Experimental conditions: solvent system: hexane/ethyl acetate/methanol/10 mM HCl (6 : 4 : 5 : 5) where the organic stationary phase containing CS at 10 to 60 mM as indicated; samples: (±)-DNB-leucine 125–1000 mg dissolved in 10–45 mL of solvent. (For other conditions, see the Figure 1 caption.)

$$D_0 = [A_{\pm}]_{\text{org}}/[A_{\pm}]_{\text{aq}} \quad [2]$$

$$K_{f\pm} = [\text{CSA}_{\pm}]_{\text{org}}/[\text{CS}]_{\text{org}}[A_{\pm}]_{\text{org}} \quad [3]$$

where D_0 is the partition coefficient of the analyte in a CS-free solvent system (this is also called the parti-

tion ratio) and D_{\pm} is the partition coefficient in a CS-containing solvent system. From these equations, the partition coefficient of the analyte is given by the following equation:

$$D_{\pm} = D_0(1 + K_{f\pm}[\text{CS}]_{\text{org}}) \quad [4]$$

Figure 4 Separation of DNB-leucine racemate by pH-zone-refining CCC. Experimental conditions: apparatus: see the Figure 1 caption; solvent system: methyl t-butyl ether/water; stationary phase: upper organic phase to which trifluoroacetic acid (40 mM) and CS (40 mM) were added; mobile phase: lower aqueous phase to which aqueous ammonia was added to 20 mM; sample: (±)-DNB-leucine 2 g; flow rate: 3.3 mL min⁻¹; revolution: 800 rpm; analysis: chirality by analytical HSCCC (see Figure 1) and pH by a portable pH meter. Note that the analysis of the fraction from the mixing zone (middle chromatogram) shows three peaks corresponding to (-)-DNB-leucine, impurity and (+)-DNB-leucine from left to right.

Figure 5 Schematic diagram of simple chemohydrodynamic equilibrium between the racemates (A_{\pm}) and chiral selector (CS) in the separation column.

Here, $[CS]_{org}$ is the difference between the initial concentration of the CS and the concentration of the CSA_{\pm} complex, i.e.:

$$[CS]_{org} = [CS]_{initial} - [CSA_{\pm}]_{org} \quad [5]$$

When $[A_{\pm}]_{org} \ll [CS]_{initial}$, $[CS]_{org}$ approaches $[CS]_{initial}$ hence, eqn [4] may be rewritten:

$$D_{\pm} \approx D_0(1 + K_{f\pm}[CS]_{initial}) \quad [6]$$

The validity of eqn [6] has been examined by a series of experiments, the results of which indicated that the separation factor (D_+/D_-) is increased as expected by increasing the concentration of chiral selector in the stationary phase (Figure 2).

For computation of K_f , eqn [6] can be modified into a more convenient form:

$$(D_{\pm} - D_0)/D_0 \approx K_{f\pm}[CS]_{initial} \quad [7]$$

where D_{\pm} and D_0 can be computed from the chromatograms obtained with and without the chiral selector in the stationary phase.

Using eqn [7] the formation constant ($K_{f\pm}$) has been determined by a series of experiments where small amounts (0.1–0.2 mg) of enantiomers were separated at various CS concentrations in the stationary phase. **Figure 6** is drawn by plotting the $(D_{\pm} - D_0)/D_0$ values from each enantiomer against the initial CS concentration in the stationary phase where the formation constant is computed from the slope of the straight line. These results indicate that the method is useful for computing the formation constants of various analyte-CS pairs.

General Chemodynamic Model in Chiral CCC

This second model deals with more generalized condition where the ionic analytes are dissociated in the aqueous mobile phase. This approach can be useful for predicting the feasibility of chiral resolution by pH-zone-refining CCC.

In Figure 5, which shows the chemodynamic equilibrium in a portion of the separation column, if the analytes are ionizable (e.g. acids) they will be partially dissociated to form anions $[A_{\pm}]_{aq}$ which are almost insoluble in the organic phase.

In this equilibrium state, the following set of equations is given for each racemate:

$$D_{\pm} = ([A_{\pm}H]_{org} + [CSA_{\pm}H]_{org}) / ([A_{\pm}H]_{aq} + [A_{\pm}^-]_{aq}) \quad [8]$$

$$D_0 = [A_{\pm}H]_{org} / [A_{\pm}H]_{aq} \quad [9]$$

$$K_a = [A_{\pm}H]_{aq} / [A_{\pm}^-]_{aq} [H^+]_{aq} \quad [10]$$

$$K_{f\pm} = [CSA_{\pm}H]_{org} / [CS]_{org} [A_{\pm}H]_{org} \quad [11]$$

where D_{\pm} , D_0 , K_a , and $K_{f\pm}$ represent the partition coefficient, the partition ratio, the dissociation constant, and the CS-complex formation constant for each racemate, respectively. From these equations, we obtain:

$$pH_{Z\pm} = pK_a + \log\{D_0/D_{\pm}(1 + [CS]_{org}K_{f\pm}) - 1\} \quad [12]$$

In pH-zone-refining CCC, the peak resolution is mainly determined by the difference in pH between

Figure 6 Determination of formation constant of CS-DNB-amino acids by the standard HSCCC technique. The diagram was produced by plotting $(D_{\pm} - D_0)/D_0$ (eqn [7]) against the initial CS concentration in the organic stationary phase. The slope of each line indicates the formation constant (K_f) of the corresponding enantiomer.

the two zones, i.e.:

$$\Delta p H_{Z\pm} = \log\left\{\frac{[CS]_{org/Z+} K_{f+} + 1 - D_0/K_r}{[CS]_{org/Z-} K_{f-} + 1 - D_0/K_r}\right\} \quad [13]$$

where $[CS]_{org/Z+}$ and $[CS]_{org/Z-}$ are the free CS concentrations in the A_+ and A_- zones, respectively. When $K_{f+} > K_{f-}$, $[CS]_{org/Z+} < [CS]_{org/Z-} < [CS]_{initial}$. Eqn [13] indicates that chiral resolution can be improved by increasing D_0/K_r and/or choosing the CS with a large K_{f+}/K_{f-} value. It also implies that increasing the CS concentration will yield higher peak resolution.

Advantages of Chiral CCC

Countercurrent chromatography can be applied to the separation of enantiomers by dissolving a suitable chiral selector in the liquid stationary phase in analogy to binding the CS to the solid support. The HSCCC technique has the following advantages over the conventional chromatographic technique using a solid stationary phase:

1. The method permits repetitive use of the same column for a variety of chiral separations by choosing appropriate chiral selectors.
2. Both analytical and preparative separations can be performed in a standard CCC column by adjusting the amount of CS in the liquid stationary phase. The method is cost effective especially for large scale preparative separations.
3. The separation factor and peak resolution can be improved by increasing the concentration of CS in the stationary phase.

4. The method is very useful for investigation of the enantioselectivity of the chiral selector including determination of formation constant and separation factor.

5. pH-Zone-refining CCC can be applied to chiral separation allowing a large scale separation in a shorter separation time.

Methods for obtaining optically active compounds in enantiopure form are commonly classified into three categories: utilization of chiral pool starting materials (stereoselective multistep synthesis), creation of chirality from achiral precursors (asymmetric synthesis) and separation of racemates into their enantiomer constituents (resolution). This last method can be carried out in a variety of ways: crystallization processes, chromatography of racemates on chiral stationary phases and kinetic resolution mediated by chiral reagents or enzymes.

The crystallization methods comprise several variants: (1) direct crystallization of enantiomer mixtures, (2) separation of diastereoisomer mixtures – the so-called classical resolution – and (3) crystallization-induced asymmetric transformation. The first two were discovered by Louis Pasteur in 1848 and 1853, respectively. The third was first reported in 1913. At the turn of the 21st century, these methods are in wide use in laboratory-scale separations as well as in industry for the preparation of pharmaceutical and agrochemical active principles. To cite but a few examples, hundreds to thousands of tonnes of commercially important materials such as (–)-menthol, (S)-(+)-naproxen, L- α -methyldopa, D-phenylglycine and the pyrethroid insecticide deltamethrin are produced by such methods.

In the context of enantiomer separations crystallization techniques are attractive for several reasons. Firstly, in many instances they are more straightforward and more economical than any other method. Secondly, these methods, once considered old-fashioned, have, during the past two decades, been greatly improved in their rationale and efficiency, as a consequence of a better knowledge of the properties upon which separations by crystallization are based: identification of racemate types, utilization of phase diagrams describing solid-liquid equilibria. Thirdly, these methods apply not only to the resolution of racemates (i.e. 1 : 1 mixtures of *d* and *l* enantiomers), they can also be used for obtaining pure enantiomers from nonracemic (partially resolved) mixtures, regardless of their origin. And finally, the so-called crystallization-induced asymmetric transformation overcomes the inherent 50% yield limitation of a resolution, permitting up to 100% of a racemic material to be converted into one enantiomer in a single stage.

Enantiomer Mixtures

This section deals with crystallization methods allowing pure enantiomers to be prepared from partially resolved mixtures or from racemates without the help of any chiral auxiliary reagent.

Phase Diagrams of Enantiomer Systems

We call enantiomer systems mixtures containing the two mirror-image *d* and *l* components in any ratio, either without solvent (binary (*d*, *l*) mixtures), or in the presence of a solvent (ternary (*d*, *l*, Σ) mixtures). Depending on the nature of the crystal phases which may coexist with the liquid (melt or solution), three categories of enantiomer systems have been identified.

In the first category, which represents 5–10% of cases, the enantiomers crystallize separately from one another (homochiral crystallization, spontaneous resolution). A solid (*d*, *l*) system then consists of a mechanical mixture of *d* and *l* crystals in a ratio corresponding to their respective mole fractions (*x*; 1 − *x*). The melting point phase diagram shows a simple eutectic at *x* = 0.5 (racemate composition). Such a (*d*, *l*) system is said to be a conglomerate of enantiomers (Figure 1A). In a conglomerate, the racemate has a melting point about 30 K lower than those of its pure enantiomers. Its solid-state infrared spectrum is identical with the solid-state spectrum of a pure enantiomer, because the infrared spectrometer does not make a difference between right- and left-handed crystals. Since most binary mixtures of enantiomers

Figure 1 Binary melting point phase diagram for enantiomer systems. (A) Conglomerate; (b) racemic compound with $T_R < T_A$, eutectic at $x = 0.3$ and 0.7 ; (c) racemic compound with $T_R > T_A$, eutectic at $x = 0.1$ and 0.9 . On recrystallization, a solid mixture *M* in which the mole fraction of the major enantiomer (here *d*) is 0.8 (enantiomeric excess $ee = 60\%$) can give this enantiomer in pure form in cases (A) and (B), the maximum yield being given by the ratio NA/EA ; in case (C) only the racemic compound can be obtained (see text).

behave ideally in the liquid state, the liquidus curves of a conglomerate phase diagram can generally be accurately calculated by means of the Schröder-van Laar equation, where T_A and ΔH_A are the temperature and enthalpy of fusion, respectively, of a pure

enantiomer, and R is the gas constant. This equation gives the melting temperature T of a mixture in which x represents the mole fraction of the major enantiomer:

$$\ln x = \frac{\Delta H_A}{R} \left(\frac{1}{T_A} - \frac{1}{T} \right)$$

In the second, main category of enantiomer systems, representing 90–95% of cases, the d and l enantiomers crystallize together to form an ordered 1:1 compound, called a racemic compound (heterochiral crystallization). Typical binary phase diagrams corresponding to this case are shown Figure 1(B) and (C). The melting point T_R of the racemic compound can be either lower or higher than that of the pure enantiomers (however, on average, the difference between T_R and T_A rarely exceeds ± 20 K). The solid-state infrared spectrum of a racemic compound is different from that of a pure enantiomer. This is a simple way of distinguishing between a racemic compound and a conglomerate (in addition to the melting point criterion). In such systems, a partially resolved solid consists of a mechanical mixture of two crystal phases, the racemic compound, in amount $r = 2(1 - x)$, and the enantiomer in excess, in amount $ee = 2x - 1$. In Figure 1(B) and (C) the liquidus curves for the enantiomer branches are calculated by means of the Schröder–van Laar equation, while the racemic compound branch is calculated by a similar equation first given by Prigogine and Defay, where T_R and ΔH_R are the temperature and enthalpy of fusion, respectively, of the racemic compound:

$$\ln 4x(1 - x) = \frac{2\Delta H_R}{R} \left(\frac{1}{T_R} - \frac{1}{T} \right)$$

In the last category of enantiomer systems, called pseudoracemates, there is almost no chiral discrimination between the d and l species which co-crystallize more or less at random within the same lattice to form a solid solution. In a pseudoracemate, a partially resolved sample consists of a single crystal containing the d and l enantiomers in a ratio (x ; $1 - x$). Such systems are, fortunately, not common. They may occur with rod-shaped or quasi-spherical molecules (e.g. camphor). They do not lend themselves easily to separation by crystallization techniques, and for this reason they will no longer be considered here.

Solubility Rules Derived from Binary-phase Diagrams

In the absence of temperature- or solvent-dependent polymorphism, the solubility rules that govern the

behaviour of enantiomer mixtures on crystallization can be simply derived from the binary phase diagrams depicted in Figure 1. The component which can be obtained upon crystallization will be either the racemic compound, or the enantiomer in excess, depending on the composition of the starting mixture with respect to the closest eutectic of the phase diagram. Thus, recrystallization of mixture M , having $x = 0.8$ ($ee = 60\%$) can give the major enantiomer in pure form in cases (A) and (B). The maximum possible yield is given by $NE/EA - 60\%$ in case (A), and only 33% in case (B). In case (C), recrystallization of M can only afford the racemate in a maximum yield NE/RE . In this case the enantiomeric enrichment takes place in the liquid, but under equilibrium conditions the highest attainable purity is that of the eutectic. In other terms, in a partially resolved conglomerate, it is always possible to recover the major enantiomer in a yield equal to the ee of the starting material, whereas in a racemic compound the outcome of the crystallization will depend on the enantiomeric composition of the starting material and on that of eutectic; even in relatively favourable cases such as that depicted in Figure 1(B), the maximum possible yield will be lower than the ee of the starting material.

Ternary Phase Diagrams

For applications in which accurate quantitative data are required (e.g. optimization of large-scale recrystallizations), it is preferable to utilize ternary (solubility) phase diagrams (d, l, Σ). Solubility phase diagrams are 3D triangular prisms where each face is a binary melting point phase diagram, (d, l), (d, Σ) and (l, Σ). It is customary to convert this 3D representation into a 2D one by keeping one of the variables fixed, most often the temperature. Accordingly, a horizontal slice of the prism generates the usual triangular isotherm describing the solid–liquid phase equilibria at given T . This is illustrated in Figure 2(A), for a conglomerate. In order to facilitate the use of such triangular isotherms, it is convenient to adopt a system of cartesian axes (C, E), where C represents the concentration and E the excess of enantiomer, expressed in the same dimensionless unit (generally in weight %); C and E are defined as follows:

$$C = \frac{d + l}{d + l + \Sigma} \times 100 \quad E = \frac{d - l}{d + l + \Sigma} \times 100$$

Typical ternary isotherms for a conglomerate and a racemic compound are shown in Figure 2(B) and (C), respectively. In a conglomerate the solubility of the racemate is normally twice the solubility of each

Figure 2 (A) 3D-representation of a $\{d, l, \Sigma\}$ system and the corresponding 2D-isotherm, for a conglomerate. The composition of a ternary system X is conveniently defined by its cartesian coordinates (C, E) . Note that $E/C = ee$, the usual enantiomeric excess, defined as $ee = (d - l)/(d + l)$; (B) and (C) represent ternary isotherms that correspond roughly to the binary phase diagrams (A) and (B) of Figure 1. On recrystallization, mixture M will only afford the major enantiomer in pure form if the composition of the ternary system is comprised between N and P , the maximum yield being obtained for system N (see text). In diagram (C), e represents the ee of the ternary eutectic E .

individual enantiomer, unless special circumstances, such as common ion effects or aggregation phenomena, decrease or increase the solubility ratio with respect to its normal value. **Figure 2(B)** and **(C)** roughly correspond to the binary phase diagrams of **Figure 1(A)** and **(B)**, respectively. On recrystallization of mixture M , the major enantiomer d can be obtained between N and P , for instance from system O . However, the best yield Y in pure d will be obtained from system N , at concentration C_N (in weight %):

$$Y = \frac{NE}{AE} \times \frac{100}{C_N}$$

For a conglomerate the above calculated yield is the same as that derived from the binary phase diagram, $Y = NE/AE$. For a racemic compound, Y calculated from the ternary isotherm is usually very close to that derived from the binary phase diagram because in such systems the ee of the eutectic does not change

significantly with temperature, except in the case of polymorphism or of solvation.

This is why information on the type of enantiomer system and, in particular, on the location of the eutectics in racemic compound phase diagrams is of great importance when the purification of partially resolved mixtures by crystallization techniques is undertaken. When the phase diagram of the considered system is not favourable (e.g. as in **Figure 1C**), recrystallization should be avoided and it may be advisable to postpone the purification to a next step, or to seek derivatives having more favourable phase diagrams. These concepts are particularly useful for the final purification of enantiomers prepared by asymmetric synthesis or chiral chromatography.

Direct Crystallization of Racemates

Separation of enantiomers by direct crystallization of their racemate is an attractive method, because no

costly chiral auxiliary is required. Such resolutions only apply to conglomerates. Essentially two main types of methods are then available. In the first of these the two enantiomers are allowed to crystallize simultaneously from a solution or melt which is always close to the racemic composition. In the second, called entrainment, the crystallization of a single enantiomer is promoted from a supersaturated solution or supercooled melt which is not allowed to come to equilibrium.

Simultaneous Crystallization

Although hand-sorting of the *d* and *l* crystals (as originally performed by Pasteur on sodium ammonium tartrate) can occasionally be a useful technique, the localization of the crystallization of each enantiomer on suitably disposed *d* and *l* seeds represents an improvement of greater practical interest. In small-scale preparations, one can utilize a small number of *d* and *l* seeds sufficiently separated from one another in the same crystallizer, and the large crystals which are eventually formed are collected manually. Large-scale applications utilize pairs of crystallization chambers, each one being loaded with a large amount of seeds of one enantiomer. The system is then continuously fed with a circulating, slightly supersaturated, racemic solution. Such processes have been proven to be valuable for continuous large-scale productions such as those developed by Haarmann & Reimer for (–)-menthol (resolved as its benzoate), and Merck for L- α -methyldopa (resolved as its nitrile precursor).

Entrainment

The entrainment method takes its origin in experiments performed by Gernez in 1866, showing that a supersaturated solution of sodium ammonium tartrate, when seeded with a particle of (+) salt, only yielded crystals of that salt. The resolution by entrainment is a batch process, which rests on the control of the crystallization rates of the two enantiomers, and implies the utilization of ternary phase diagrams, such as that shown in Figure 3. A solution *M*, supersaturated with respect of both enantiomers, and containing a small excess (*E* g%) of one of them (here, *l*) is seeded with crystals of that enantiomer. Crystallization is then allowed to proceed until the solution has reached composition *N*. At this point, the rotation of the solution is approximately equal and opposite in sign to that of the starting solution, and the *l* enantiomer that has crystallized amounts to twice its excess in the original solution *M* (i.e. $\approx 2E$ g%). At this stage, the crystals are separated off, and the same

Figure 3 Principle of the entrainment process. In the cycle *MNPQ*, *MN* and *PQ* correspond to the crystallization of enantiomers *l* and *d*, respectively; *NP* and *QM* correspond to the loading of racemic material. In commercial processes, 20–90 crystallizations are commonly performed.

weight of racemic material is added to the filtrate and dissolved by heating. This results in a new supersaturated system of composition *P*, symmetrical to *M*, where the *d* enantiomer is now in the same excess as was the *l* in the previous experiment. Seeding with the *d* form and crystallization up to *Q* then yields $\approx 2E$ g% of *d*, and addition of the same weight of racemate allows the return to *M*, and so forth.

In practice, the economics of the process depends on the amount of material collected after each crystallization, which should represent at least 10–15% of the solute, and on the number of cycles which can be performed; this number is limited by the build-up of impurities which follows the addition of fresh racemate at each step, and which may eventually disturb the crystallization kinetics. The Roussel-Uclaf and Zambon processes for the manufacture of the chloramphenicol and thiamphenicol intermediates shown in Figure 3 are well-known industrial applications of resolution by entrainment. The method is also of great value for laboratory-scale resolutions, especially at the 100 g to kg scale.

For low-melting conglomerates, the entrainment can also be effected without solvent, in a supercooled melt. Such processes are easily understood by means of the melting point phase diagrams, by considering the metastable extension of the liquidus curves below the eutectic temperature.

Diastereoisomers

The most widely used method for the separation of enantiomers, often called classical resolution, rests on the crystallization of diastereoisomers formed from a racemate (dl) and an enantiopure reagent (say, D), called a resolving agent:

It is convenient to designate with letters p (positive) and n (negative) the diastereoisomers resulting from reaction of the two constituents of like sign and opposite signs, respectively. In this convention, no account is taken of the sign of rotation of the diastereoisomers themselves, which, if needed, can be specified by adding a $+$ or $-$ subscript to the p and n descriptor. Accordingly, the above reaction yields a mixture of p (dD) and n (lD) diastereoisomers, which, for instance, can both be dextrorotatory, i.e. p_+ and n_+ . The opposite enantiomer (L) of the resolving agent would then afford with the same racemate the diastereoisomer pair p_- (lL) and n_- (dL), mirror image of p_+ and n_+ (Marckwald principle). Note that the reciprocal resolution of DL by, for instance, d , would yield a mixture of p_+ (dD) and n_- (dL).

Diastereoisomeric salts, formed from simple acid-base reactions, are central to such resolutions, although covalent diastereoisomers (esters, amides, etc.) are also occasionally resolvable by crystallization. To cite but a single example, the DSM company resolves DL-phenylglycine by crystallization of its diastereoisomeric salts with (+)-10-camphorsulfonic acid, to produce the D-enantiomer required for the manufacture of the antibiotic ampicillin, at a scale of more than 1000 tonnes per year.

Diastereoisomeric inclusion complexes, in which the resolving agent is a chiral crystalline host lattice, represent an interesting alternative for the resolution of substances that cannot form salts, or do not possess functional groups suitable for formation of covalent diastereoisomers.

Phase Diagrams and Solubility Rules

Diastereoisomers p and n are distinct compounds and exhibit different structures in the crystal state. It fol-

lows that all physical properties involving the crystal themselves and the crystal/liquid or crystal/gas equilibria, such as melting points, solubilities, sublimation properties, crystal densities, etc., are different for the p and n species of a given pair. However, the possibility of separating p and n diastereoisomers by crystallization of their 1 : 1 mixture, resulting from the reaction of a racemate with a resolving agent, does not depend only on the properties of the pure p and n compounds: it rests primarily on the existence of favourable solid-liquid phase equilibria for the binary (p, n) or ternary (p, n, Σ) systems. The phase diagrams of diastereoisomer systems (Figure 4) are basically similar to those of enantiomer systems. There exist, however, several important differences between them: (1) the phase diagrams of diastereomer mixtures are not symmetrical; (2) in contrast to enantiomers, diastereoisomers preferentially form eutectics or solid solutions (Figure 4(A) and (C), respectively); (3) the occurrence of 1 : 1 (pn) addition compounds depicted in Figure 4(B) is by far less than that of (dl) racemic compounds.

Only diastereoisomer systems forming eutectic phase diagrams are suitable for resolution by crystallization. In the solubility isotherm of Figure 4(A), 1 : 1 (p, n) mixtures will afford the pure less soluble diastereoisomer (here p) if the crystallization is carried out between N and P , for instance from solution O . The best yield however will be obtained from solution N . This yield is given by:

$$Y = \frac{NE}{Ep} \times \frac{100}{C_N}$$

where C_N is the concentration of solution N . Since the p/n ratio in the ternary eutectic is usually close to that of the binary eutectic, Y is not very different from RE/AE in the melting point phase diagram. The best systems are those in which the eutectic is close to the edge of the phase diagram, and the maximum value of $Y = 50\%$ is approached when E is closed to one of the pure components. The occurrence of such good systems has been estimated at 20–25% of diastereoisomer mixtures. It is important to recognize that in such cases one or two crystallizations are normally sufficient to obtain the less soluble diastereoisomer in pure form.

Systems in which a 1 : 1 [p, n] compound exists, as in Figure 4(B), are totally unsuitable for resolution because crystallization of a 1 : 1 mixture will afford the 1 : 1 compound. Some resolution is possible with systems forming a solid solution, as shown in Figure 4(C), providing that the solubility difference between the pure components is sufficiently large. Most

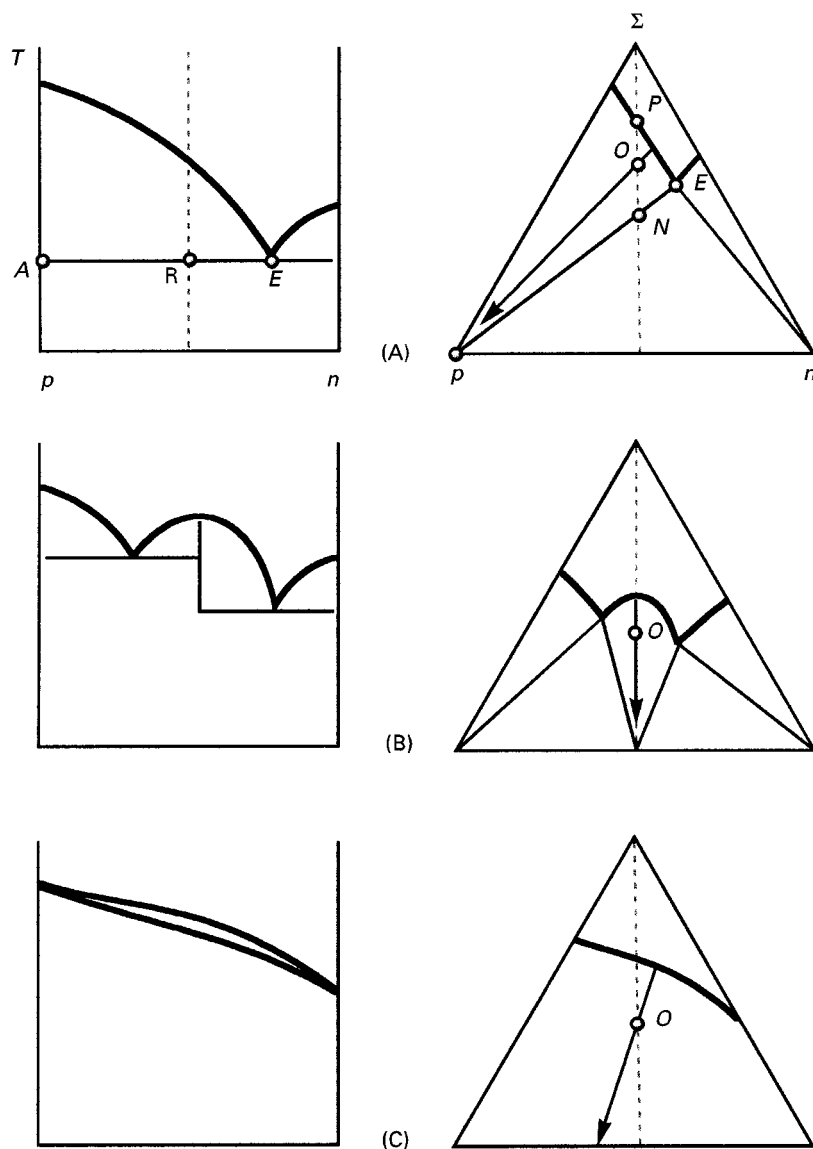

Figure 4 Melting point (left) and solubility (right) phase diagrams for diastereoisomer systems. (A) eutectic; (B) 1 : 1 addition compound; (C) solid solution. The arrows indicate the nature of the solid obtained from crystallization of a system of composition O .

often, however, the enrichment is very modest and utilization of systematic fractional crystallization techniques is required. These techniques are very tedious and time-consuming and this is why resolution of (p, n) systems forming solid solutions is not recommended unless alternative methods cannot be found. Note that diastereoisomeric lattice inclusion complexes are more prone to form solid solutions than the other types of diastereoisomers and often need repeated crystallizations to reach good enrichments. In such cases rather than purify the diastereoisomers, it may be advisable to complete the purification on the partially resolved enantiomers, along the lines indicated above.

Resolving Agents

In order to set up practical process for the separation of diastereoisomeric salts, initially a system forming a eutectic must be selected. This leads to the choice of the resolving agent and of the solvent. Next the crystallization conditions are optimized by means of phase diagrams along the lines discussed above. A classical resolving agent is a chiral acid or base available in bulk quantities at low price, and which has a propensity to form crystalline diastereoisomers when combined with racemic bases or acids. **Table 1** lists some of the most common resolving agents for salt formation. Other, more specialized, resolving agents for the separation of

Table 1 Common resolving agents

diastereoisomers by chromatography or for analytical purposes (nuclear magnetic resonance spectroscopy) are not mentioned here. For important commercial applications, it may be appropriate to design new resolving agents: for example, the *N*-alkyl-D-glucamine family (prepared from D-glucose) has been developed by Syntex as a substitute for cinchonidine for the large-scale resolution of naproxen (over 1000 tonnes per year). There are no clear guidelines allowing the prediction of a good resolving agent for a given substrate. This is not really a serious problem because the number of available resolving agents, being very limited, generally allows systematized protocols to identify the best ones very quickly.

Salts usually need polar solvents to crystallize, and a statistical survey of solvents used in over 800 such resolutions indicate that anhydrous or aqueous acetone and alcohols (ethanol, methanol, 1- and 2-propanol, 1-butanol), and water feature in 80% of cases. The presence of water may be necessary whenever the salts crystallize as hydrates. This is why 95% ethanol (rather than absolute ethanol) is to be preferred during the selection of a resolving agent.

Interesting achievements in the area of chiral host lattices have been reported during the last decade. A small number of chiral substances that form diastereoisomeric crystalline inclusion complexes with a variety of guests have been identified. In addition to the alkaloid brucine, which has been utilized for resolving, at least partially, chiral halogenoalkanes (including CHFCIBr) and, more recently, acetylenic alcohols and cyanohydrins, several new hosts have been discovered, among which readily available diols prepared from tartaric acid seem to have the greatest potential as resolving agents.

Crystallization-induced Asymmetric Transformations

The 50% yield limit of a resolution can be exceeded if the diastereoisomers can be equilibrated in the solu-

tion (i.e. $dD \rightleftharpoons lD$) at a rate faster than the crystallization of the least soluble one. Such a phenomenon was first reported by Leuchs in 1913; he isolated in 94% yield a single diastereoisomeric salt after reaction of an easily racemizable racemic acid with brucine. In addition to the requirement that the diastereoisomers must epimerize easily, processes of this type can only be successful if the diastereoisomer system belongs to the eutectic type. In **Figure 5**, the starting material has composition *O* (overall concentration C_0). In the liquid phase, the composition of the diastereoisomer mixture in chemical equilibrium is indicated by *L*, which in the case shown is slightly shifted towards the *n* species. The final equilibrium state is featured by *N*, representing the overall composition of the system at the end of the process. System *N* consists of pure solid *p* in equilibrium with liquid *L*. The yield in diastereoisomer *p* is proportional to LN/Lp , and can be derived from C_0 and the composition of the liquid in equilibrium (C_{eq}):

$$Y = \frac{(C_0 - C_{eq})}{(100 - C_{eq})} \times \frac{100}{C_0}$$

Accordingly, yields approaching 100% can only be obtained in poor solvents, in which C_{eq} is very small. Typically, $C_{eq} = 2$ g% and $C_0 = 20$ g% would give a *Y* of nearly 92%. In contrast to the case of a classical resolution, the yield does not depend directly on the location of the eutectic. However, it is the distance between the eutectic *E* and the equilibrium solution *L* which provides the driving force for the process, and this is why, again, a eutectic close to the edges of the phase diagram is preferable.

There are many examples of such processes in industry. They can be performed on diastereoisomeric salts (e.g. phenylglycine camphorsulfonate) as well as on covalent diastereoisomers (e.g. in the Roussel-Uclaf synthesis of the insecticide deltamethrin).

Figure 5 Crystallization-induced asymmetric transformation of diastereoisomers. In the solubility isotherm shown, *L* represents the composition of the liquid in which the two diastereoisomers are in chemical equilibrium (here with a slight excess of *n*). This liquid is itself in physical equilibrium with the solid, consisting of pure *p*. After completion of the chemical and physical equilibrations, the starting system *O* will be converted into the final system *N*, consisting of solid *p* in equilibrium with liquid *L*.

Crystallization-induced asymmetric transformations of enantiomers forming conglomerates can also be carried out by combining entrainment techniques with simultaneous racemization of the substrate in the solution. Although a number of examples have been described, and a number of patents have been filed, only a few processes of this type have reached commercial application.

Future Prospects

The understanding of phase equilibria in enantiomer and diastereoisomer systems is a central question, not only in view of its practical relevance to separation processes, but also because it may shed light on some of the mechanisms governing molecular recognition in condensed matter. Among the numerous unsolved questions, that of the prediction of racemate types is perhaps one of the most challenging. Recently, it has been shown that, in theory, conversion of racemic compounds into conglomerates could be achieved for some racemates by crystallization under high pressure. An experimental verification of this prediction would be of great importance in extending the possibilities of resolving racemates by direct crystallization.

Cyclodextrins and Other Inclusion Complexation Approaches

Introduction

Cyclodextrins are cyclic nonreducing oligosaccharides containing from six to twelve glucose units in a C-1 chair conformation, bonded through α -(1,4) linkages (Figure 1). The glycopyranose units are arranged in the shape of a hollow truncated cone. The larger opening of the molecule is surrounded by the secondary (C-2 and C-3) hydroxyl groups, while the primary (C-6) hydroxyl groups constitute the smaller end of the cone.

Since all the primary and secondary hydroxyl groups are located at the outside of the molecule, the exterior faces are hydrophilic. The interior cavity, essentially comprised of methylene linkages and glycosidic oxygen bridges, is relatively hydrophobic in comparison with polar solvents such as water. Furthermore, the glycosidic oxygen bridges produce a high electron density, giving the interior of the cavity a slightly Lewis-base character.

The three smallest cyclodextrin homologues are readily commercially available:

- α -cyclodextrin (cyclohexamylose);
- β -cyclodextrin (cycloheptamylose);
- γ -cyclodextrin (cyclooctamylose);

The basic property of cyclodextrins is their ability to form selective inclusion complexes with a broad variety of organic and inorganic molecules.

The formation of inclusion complexes is in general determined by the ability of the guest molecule to closely fit the cavity of the cyclodextrin. However, the polarity of the guest molecule also plays an important role.

Inclusion complexes are usually formed in the presence of water or in water mixed with organic modifiers.

Figure 1 Numbering of carbon atoms in the cyclodextrin ring structure.

One of the first effective uses of cyclodextrins in chromatography was as mobile phase additive in thin-layer chromatography. In the mid-1980's a process was developed to produce stable cyclodextrin high performance liquid chromatographic (HPLC) phases. Nowadays, native α -, β - and γ -cyclodextrin, as well as a variety of derivatized cyclodextrin HPLC columns are commercially available. Also many cyclodextrin-based capillary gas chromatography (GC) columns are on the market. With the growing importance of capillary electrophoresis in chiral separations, the use of native cyclodextrin and cyclodextrin derivatives as an electrolyte additive steadily increases.

Cyclodextrins in HPLC Applications

Native cyclodextrin HPLC columns were deliberately designed to be used in the reserved-phase mode of operation, in order to take full advantage of the host-guest complexation capabilities of the molecule.

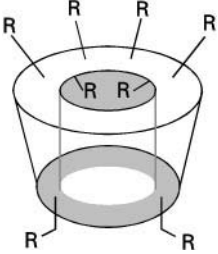

In a more recent and somewhat different experimental approach, the inclusion properties are suppressed by using a non-hydrogen bonding, polar organic solvent (e.g., acetonitrile) as the main component of the mobile phase. Acetonitrile has the tendency to occupy the cavity and seems to enhance hydrogen bonding between the hydroxyl groups on the cyclodextrin and hydrogen bonding groups on the chiral analyte.

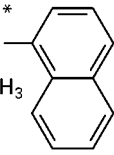

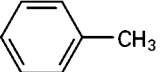

In this so-called polar organic mode of operation, the addition of small amounts of glacial acetic acid and triethylamine is used as a tool to enhance enantioselectivity. On the other hand, the addition of a hydrogen bonding solvent such as methanol allows reduced retention of strongly retained molecules. This technique produces some unusual enantioselectivities that certainly enhance the usefulness of native cyclodextrin phases.

Furthermore, a variety of cyclodextrin derivatives has been immobilized on a chromatographic support, which can be used under normal as well as under reversed-phase conditions. The most popular commercially available derivatized cyclodextrin chiral selectors are listed in Table 1.

Mobile Phase Design and Parameter Optimization

Because complex stability constants usually have greater values in water or water-organic organic solvent mixtures than in a pure organic medium, native cyclodextrin columns are predominantly used in the reserved-phase mode. Ethanol, propanol, 1,4-dioxane, dimethyl sulfoxide, dimethyl formamide,

methanol and acetonitrile have been used as organic modifiers. However, methanol and acetonitrile are most commonly used. It is difficult to predict in advance which of these two modifiers will produce the best separation in any given case. In many cases, pH and ionic strength of the aqueous part of the mobile phase are even more important than the choice of the organic modifier.

The following factors influence enantioselectivity.

Ionic strength With an eluent composed of a mixture of 5 millimolar tetrabutylammonium hydrogen-sulfate (TBAHS) in water and methanol in an 80–20 volume ratio, experiments were performed on a β -cyclodextrin Astec column (Cyclobond®) and a similar Merck column Merck (Chiradex®). The only difference between both stationary phases is the chemistry used to attach the β -cyclodextrin to the silica matrix.

In these initial experiments, especially on the Cyclobond® column, a poor peak shape for different products was observed. This effect was less pronounced on the Chiradex® column but it also occurred for some products. The origin of the poor peak shapes can have different causes, as for example an insufficient shielding of residual silanol groups. Therefore, the effect of the tailing reducer concentration was investigated.

Figure 2 illustrates the effect of the tailing reducer concentration on the retention factor and the resolution of miconazole (R14889). In this figure, the resolution factor based on the location of the valley point between two peaks is used. The resolution parameter (Auflösung (*g*)) is defined to evaluate the degree of separation between two partially resolved enantiomers. This measuring principle is based on the location of the valley point between two adjacent peaks. It is a useful and, from a measurement viewpoint,

Figure 2 Influence of tailing reducer concentration on the retention factor and valley point resolution ▲, Cyclobond®; ●, Chiradex®. Solute:

easy evaluation technique for characterizing the separation degree between two peaks.

If we analyse **Figure 2**, it is easy to conclude that ionic strength has a strong effect on the chromatographic behaviour of the investigated chiral molecule. It is furthermore perfectly clear that the influence of ionic strength on the retention factor is more pronounced on the Chiradex® than the Cyclobond® column. However, for both types of stationary phase a constant value is observed above a tailing reducer concentration of 20 mmol. At low TBAHS concentration, the smallest resolution values are measured on

the Cyclobond® column. Also, the ionic strength required to reach the highest resolution value is different for both columns.

Further experiments dealing with the effect of ionic strength on peak shape and chromatographic behaviour have demonstrated that for each individual column type–tailing reducer combination it can be very helpful to investigate this parameter thoroughly. However, to save time, we nowadays start our chiral method development work on cyclodextrin-based columns with tailing reducer concentrations between 30 and 50 mmol, because we have experienced that with these values there is in general a good chance of being successful.

Type of tailing reducer The acetic acid salt of triethylamine is popular as tailing reducer in reversed-phase chromatography. Instead of using acetic acid to adjust the pH value of an aqueous triethylamine solution, we investigated the usefulness of some other organic and inorganic acids. At first we did not expect any influence of the type of counterion on enantioselectivity, but some preliminary experiments showed a distinct effect, worthwhile to investigate further. Therefore, we examined about 30 products belonging to different product classes. As mobile phase, a mixture of 20 vol% of methanol and 80 vol% of 50 mmol aqueous triethylamine solution adjusted to a pH value of 2.5 with respectively hydrochloric, hydrobromic, phosphoric, perchloric, sulfuric, trifluoroacetic and oxalic acids was used.

For all the investigated products, the largest retention factors were observed for the triethylamine solution adjusted to the desired pH value with sulfuric and oxalic acids. Also with sulfate as counterion, the largest number of investigated products was partially or completely resolved. Compared to the other acids, with trifluoroacetic and perchloric acid a smaller number of products were separated. To further investigate the observed effect, we repeated the same experiments for a series of azoles, which differed only slightly in structure. For these substances, the effect of the counterion on resolution is illustrated in **Figure 3**. See also **Table 2**.

For this product series, the results confirm the initial observations. Furthermore, **Figure 3** clearly demonstrates that even small change in molecular structure, as for example the number or position of the chlorine atoms on one of the phenyl groups of the molecule, can have a tremendous effect on the enantioselectivity.

Although for the investigated series of azoles pH adjustment with sulfuric acid in general resulted in good peak shapes and high resolution values, one peculiarity was observed. Under these experimental

Figure 3 Azoles: effect of the counterion on resolution. Experimental conditions: column: 25 cm \times 4.6 mm ID Cyclobond® (Astec); mobile phase: 50 mM triethylamine in water adjusted to pH 2.5 with different acids–methanol (80–20, v/v); flow rate: 1 mL min⁻¹, solutes; see Table 2.

conditions, R78575 was strongly retained and both enantiomers eluted as broad peaks with an irregular shape (Figure 4). On the other hand, pH adjustment of the triethylamine solution with the other acids resulted in normal peak shapes (Figure 5). This is an indication that minor differences in structure, or small variations in experimental conditions, can have a tremendous effect on the chromatographic behaviour of enantiomers.

A comparable set of experiments was subsequently performed using tetrabutylammonium hydroxide instead of triethylamine as tailing reducer. In this set of experiments, oxalic acid was excluded and perchloric acid could not be used owing to the formation of an insoluble salt with tetrabutylammonium hydroxide in the water–methanol mixture. For the whole test series of 24 different substances, sulfuric acid could be identified as the counterion that generated the highest resolution values. From a practical point of view, it is certainly an advantage that sulfate is the anion of choice. For temperatures between room temperature and 50°C the corrosion of stainless steel (316 or equivalent) is negligible for dilute sulfuric acid solutions, while the chemical resistance of this material for chloride ions (even in low concentrations), is rather limited.

In conclusion, the anionic part of the tailing reducer has a clear effect on enantioselectivity, as illus-

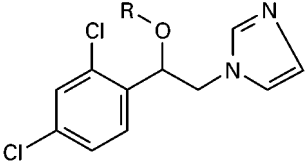

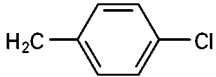

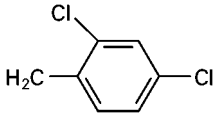

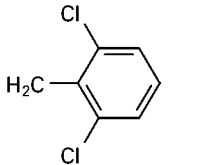

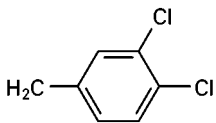

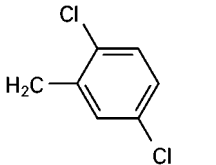

trated previously. The influence of the counterion on the retention factor and resolution of the investigated compounds can possibly be related to a difference in ability of the counterion to compete with the organic guest molecule for the hydrogen bonding sites of the cyclodextrin host.

To complete the experiments concerning the influence of the type of tailing reducer, we also found it necessary to do some tests in which the anionic part of the tailing reducer was kept identical while the cationic part was varied. In these experiments, a 30 mmol solution of tetramethyl-, tetraethyl-, tetrapropyl- and tetrabutylammonium hydroxide solution was adjusted with sulfuric acid to a pH value of 2.5 and used as mobile phase in an 80–20 volume ratio with methanol as organic modifier.

The smallest resolution values are observed for tetramethylammonium hydroxide and the highest values for tetrabutylammonium hydroxide, but compared with the influence of the anionic part of the tailing reducer the differences are far less pronounced. However, for the investigated test series, the tailing factor measured at 10% of the peak height gradually decreases with increasing chain length of the alkylammonium hydroxide.

pH Whatever type of silica-based reversed phases are used, these materials always display some acidic

surface area properties owing to residual hydroxyl groups on the silica surface. During the analysis of basic substances not only hydrophobic interactions take place, but also acid-base interactions between these acidic groups and basic functions in the analyte can be expected to occur. This type of interaction often results in increased retention combined with peak tailing. One of the possibilities to solve this problem is to adjust the pH below the pK_a value of the sample that has to be analysed. At pH values lower than $pK_a - 2$ the basic function is protonated and a salt is formed which no longer has basic properties.

Because the cyclodextrin columns are used under reversed-phase conditions, it is certainly worthwhile to investigate the effect of pH on enantioselectivity. For some monobasic molecules, the effect of pH on the retention factor is depicted in Figure 6.

Figure 6 clearly illustrates that the retention factor of the investigated products follows a typical reversed-phase pattern. At higher pH values the degree of protonation of the analyte diminishes. As a result the chance for hydrophobic interactions with the stationary phase increases and higher retention values are measured. When the pH is equal to the pK_a value of the sample, the number of protonated and nonprotonated molecules is equal. Small changes in pH around this value will immediately have an effect on the retention factor. Even the effect of small structural changes, causing some differences, in hydrophobic nature of the nonprotonated solute molecules, can be clearly observed.

R8110 has the smallest retention factor owing to the presence of a fluorine atom on the phenyl group, giving the molecule a more polar character than the other two members of the test series. The largest retention factors are measured for R7405 bearing an ethyl group on the ester function attached to the imidazole ring instead of a methyl group for R7315.

To better visualize the effect of pH variations on enantioselectivity we often use for the graphical

Figure 4 Peak shape of the different azoles. Experimental conditions: column: 25 cm \times 4.6 mm ID Cyclobond® (Astec); mobile phase: 50 mM triethylamine in water adjusted to pH 2.5 with sulfuric acid-methanol (80–20, v/v); flow rate: 1 mL min⁻¹; solutes: see Table 2.

Figure 5 Peak shape of R78575. Experimental conditions: column: 25 cm \times 4.6 mm ID Cyclobond® (Astec); mobile phase: 50 mM triethylamine in water adjusted to pH 2.5 with different acids-methanol (80–20, v/v); flow rate: 1 mL min⁻¹; solute:

representation of experimental data the degree of protonation of the solute molecules instead of pH values. For monobasic substances the ratio between protonated and nonprotonated molecules at a certain pH value can be easily calculated:

$$K_a = \frac{[\text{R-NH}_2] \cdot [\text{H}^+]}{[\text{R-NH}_3^+]}$$

$$\text{p}K_a = \text{pH} + \log \frac{[\text{R-NH}_3^+]}{[\text{R-NH}_2]}$$

(Henderson-Hasselbalch equation)

$$\text{p}K_a - \text{pH} = \log \frac{[\text{R-NH}_3^+]}{[\text{R-NH}_2]}$$

From:

$$10^{(\text{p}K_a - \text{pH})} = \frac{[\text{R-NH}_3^+]}{[\text{R-NH}_2]}$$

and:

$$[\text{R-NH}_3^+] + [\text{R-NH}_2] = 100$$

it is possible to easily calculate for each pH value the ratio between protonated and free base. For R7315, R7405 and R8110 the valley point resolution versus the percentage protonation is depicted in Figure 7.

For the investigated product series, it is clear that under the experimental conditions applied above a certain degree of protonation of the solute molecules the enantioselectivity strongly decreases. Probably due to an increase in hydrophilic character of the protonated molecules, the strength of the hydrophobic interactions between the analyte and the cavity of the cyclodextrin molecule diminishes, with a reduced enantioselectivity as a result. Within the investigated pH range, triethylamine ($pK_a = 10.72$) always remains fully protonated. Therefore, competition for hydrophobic interactions with the cyclodextrin cavity between the tailing reducer and the solute molecules has to be considered as nonexistent and can be excluded as a possible reason for reduced enantioselectivity at higher pH values.

Besides investigations on the effect of pH using triethylamine as basic substance in the aqueous part of the mobile phase, experiments have also been performed with different tetraalkylammonium hydroxides adjusted to the desired pH value with sulfuric acid. Within the same pH range, tetrabutylammonium hydroxide and triethylamine displayed comparable patterns when the valley point resolution was plotted against the percentage of protonation of the solute molecules.

For a dibasic substance (R60844) with respectively pK_a values of 5.4 and 6.7 the protonation pattern versus pH, together with the valley point resolution for two types of mobile phase additives, is given in Figure 8.

Although for the dibasic product R60844 both basic functions remain fully protonated up to a pH value of 4, the resolution continuously increases between pH 2 and 4. However, above pH 4 the enantioselectivity rapidly decreases.

For the different product series that have been examined we have observed that under the same experimental conditions, in general, higher resolution values are obtained with triethylamine than with

Figure 8 Effect of pH on the degree of protonation and resolution of a dibasic substance. —, Alpha 0; ---, alpha 1; - - - -, alpha 2; ■, TBA-OH; □, TEA. Experimental conditions: column: 25 cm \times 4 mm ID Chiradex® (Merck); mobile phase: 50 mM triethylamine in water adjusted to different pH values with sulfuric acid-methanol (80–20, v/v); and 30 mM tetrabutylammonium hydroxide in water adjusted to different pH values with sulfuric acid-methanol (80–20, v/v); flow rate: 1 mL min⁻¹; solute;

tetrabutylammonium hydroxide as mobile phase additive.

In conclusion, the stability of the inclusion complexes formed between the solute molecule and the cyclodextrin seem to be dependent on the charge of the guest molecule. Therefore, the retention as well as the degree of separation of molecules bearing an ionizable acidic or basic group can be affected by changing the pH. However, the effect of pH variations is not so easy to predict.

In the experiments performed, some products (R7315, R7405, T824, etc.) display the highest resolution values when they are present as free base or as a partially charged molecule. Other products (R60844, most of the azoles) reach maximum resolution when they are completely or nearly completely protonated. For some products the effect of pH variations within a range of 2–3 pH units is small, while for others extreme effects can be observed. Furthermore, for different types of tailing reducers the resolution versus pH profiles can have a different shape.

Therefore, the different experiments that have been performed to investigate the effect of pH on enantioselectivity clearly demonstrate that besides host-guest complexation interactions between the solute molecule and the cyclodextrin cavity, the hydroxyl groups at the outside of the cyclodextrin molecule together with reversed phase and other less predictable types of interactions certainly play an important role in the chiral recognition process.

Because small changes in pH can have a tremendous influence on the enantioselectivity, it is certainly advisable to thoroughly investigate this parameter during method development and optimization work on cyclodextrin columns.

Temperature In equilibrium-based processes, temperature plays an important role. For all investigated compounds, a very good linear relationship between the natural logarithm of the retention factor and the inverse of temperature is observed. For the products R7315 and R7405 only small differences in slope are measured. Indications that for both products the enthalpy values for solute-stationary phase transfer are very similar. The effect of temperature on the valley point resolution is given in Figure 9.

Only for R23979 was a valley point resolution of one measured for the whole temperature range between 1 and 40°C meaning that for this product the effect of temperature variation is of the same magnitude for both enantiomers. For R60844 and R7315 practically no influence on the resolution was observed between 1 and 15°C. Above that temperature, for both products the resolution value starts to decrease in a similar way. The continuous decrease of

Figure 9 Influence of temperature on the retention factor. ◆, R7315; □, R7405; ▲, R60844; ●, R23979. Experimental conditions: column: 25 cm × 4 mm ID Chiradex® (Merck); mobile phase: 30 mM triethylamine hydroxide in water adjusted to different pH values with sulfuric acid-methanol (80–20, v/v); flow rate: 1 mL min⁻¹; temperature range: 1–40°C; solutes:

the resolution value with increasing temperature observed for R7405 can be considered as a logical behaviour, because for R7405 and R7315 the smallest retention factors are measures – an indication that the binding forces between the stationary phase and these solutes are smaller than for the other products investigated. As a result, the effect of a temperature increase on the resolution is more pronounced for these compounds. However, we did not expect to observe a different effect of temperature variations for R7315 and R7405, because for both products only minor differences in enthalpy values were measured. Therefore, temperature variations probably have the same influence on both enantiomers of R7405, while the enantiomers of R7315 are affected in a different way.

In conclusion, temperature variations have an influence on the retention factor as well as on the resolution value. However, the effects observed differ from one product to another. Therefore, this parameter

has to be investigated on an individual basis during method development and optimization work.

Type and concentration of organic modifier It is known that for the reversed-phase analysis of several alkylbenzenes on chemically bonded cyclodextrin columns the type of alcohol, together with its concentration in the mobile phase, strongly influences the retention behaviour of these substances.

To investigate the effect of type of alcohol on enantioselectivity, we performed some experiments in which the normally used modifier (methanol) was replaced by the same amount of ethanol 1-propanol. For all the investigated substances, the retention factor strongly decreased with increasing chain length of the alcohol used.

The retention factors measured for an ethanol-based mobile phase are about 30–50% lower than the values observed for methanol as organic modifier. A decrease of approximately the same magnitude could be observed when ethanol was replaced by 1-propanol. Therefore, in extreme cases the retention factor drops to about 20% of the value measured for methanol, when this solvent is replaced by the same amount of 1-propanol. With increasing chain length the hydrophobicity of the alcohol increase, which enhances the chance for competition between the solvent and the analyte molecules to interact with the hydrophobic cyclodextrin cavity.

Because a strong decrease in retention time of the solutes could be observed when ethanol or 1-propanol was used as organic modifier, these solvents seem to have a greater affinity for the cyclodextrin cavity than methanol. Therefore, they will be more effective for displacing strongly retained substances from a cyclodextrin column. The manufacturers of cyclodextrin columns in fact use this property, because they recommend regenerating their columns by passing several column volumes of pure ethanol through the column, followed by pure water and then methanol.

In general, an increasing water content in the mobile phase increases both the retention and the enantioselectivity. However, for practical applications the retention factors are generally too long when mobile phases with a high water content are used, and a compromise has to be found. For our product classes we therefore use a mixture of 80 vol% of aqueous phase and 20 vol% of methanol as a typical starting mobile phase composition. If the products are too strongly retained or do not elute at all, the amount of methanol is systematically increased.

Flow rate Due to the very specific type of interactions, which play a major role in chiral recognition

processes, chiral stationary phases often display slow mass transfer characteristics. Therefore, on chiral stationary phases, flow rate can have a strong effect on the enantioselectivity. For difficult separations, lowering the flow rate certainly has to be considered as a tool to enhance enantioselectivity.

Derivatized Cyclodextrins

Native cyclodextrin columns cannot be used effectively for the separation of enantiomers under normal phase chromatographic conditions. On the other hand, different naturally occurring chiral molecules that have been derivatized are extensively and very successfully used in the normal phase mode of operation.

Triacetylcellulose, obtained by heterogeneous acylation of cellulose, was one of the first commercially available derivatives. However, the later developed and commercialized aromatic cellulose and amylose derivatives (benzoates, carbamates), compared with triacetylcellulose, are much more universally applicable. Owing to the broad applicability of the cellulose and amylose derivatives similar cyclodextrin-based stationary phases have been developed.

In our laboratories we investigated the possibilities of the derivatized cyclodextrin columns under normal as well as reversed-phase chromatographic conditions. We also compared these phases with the corresponding cellulose derivatives.

Our first experiments on the functionalized cyclodextrin phases were performed under normal phase conditions. A series of 42 products covering a broad range of organic chemistry were investigated on the *S*-naphthylethyl carbamate, the *para*-toluoyl and 3,5-dimethylphenyl carbamate cyclodextrin derivative, using *n*-hexane-2-propanol in different ratios as the mobile phase.

The results obtained were rather poor. Of the whole test series only six products were partially or completely resolved on the 3,5-dimethylphenyl carbamate column. The situation was even worse on the two other columns tested. Therefore, we decided to switch immediately to the reversed-phase mode of operation. The initially used test series of 42 products was first investigated on the three above-mentioned cyclodextrin columns with a mobile phase consisting of 0.5% ammonium acetate in water and methanol in a 30–70 volume ratio. This mobile phase composition was chosen after some preliminary experiments, which demonstrated that higher water content caused a tremendous increase in retention times. Compared with the results under normal phase conditions, the number of products separated and the degree of separation were much better on all the investigated

column types. Because earlier experiments on the native cyclodextrin phases have demonstrated that an acidic pH generally results in better separations, a 20 mM tetrabutylammonium hydrogensulfate solution (pH 2.3) was thereafter used as tailing reducer.

Owing to the well-known reversed-phase effect of retention decrease with lowering pH values, the methanol content in the mobile phase had to be reduced to 40 vol% instead of the 80 vol% used in the experiments with ammonium acetate as tailing reducer. Under these experimental conditions, the largest number of products was separated on the *S*-naphthylethyl carbamate column, although the results on the other two columns only differed slightly. It was also interesting to observe that some products, which could not be separated on native cyclodextrin, were completely resolved on one of the derivatized phases. In the next set of experiments, a 20 mM solution of respectively tetramethyl-, tetraethyl- and tetrabutylammonium hydroxide was adjusted with sulfuric acid to a pH value of 2.5 and used in combination with 70 vol% of methanol as the mobile phase. The effect of the cationic part of the tailing reducer is not clear. With tetraethylammonium hydroxide the largest number of products are partially or completely resolved, but the resolution values are in general somewhat higher with tetramethylammonium hydroxide, although the differences with the two other alkylammonium hydroxides are minimal. Only for one member of the test series was tetramethylammonium hydroxide required to obtain partial resolution.

On native cyclodextrin columns, we could clearly demonstrate the influence of the anionic part of the tailing reducer. Therefore, a similar test was done on the 3,5-dimethylphenyl carbamate cyclodextrin derivative, using 20 mM tetramethylammonium hydroxide adjusted to pH 2.5 with respectively trifluoroacetic, hydrochloric, phosphoric, (*D*)-camphorsulfonic and sulfuric acids, (*D*)-Camphorsulfonic acid has been deliberately chosen to investigate eventual additional effects by introducing chirality in the mobile phase. After pH adjustment, the aqueous phase was mixed with methanol in a 30–70 volume ratio. Some products were also tested with a 50–50 mixture of aqueous phase and methanol. Comparable with the observations on the native cyclodextrin column, and also on the functionalized cyclodextrin, pH adjustment with sulfuric acid resulted in the largest number of separations. For all the other acids, the number of partially or completely resolved products dropped to about 50% or less of the value observed for sulfuric acid. However, three products which could not be separated with one of the different acids

tested were partially resolved when (*D*)-camphorsulfonic acid was used to adjust the pH of the tetrabutylammonium hydroxide solution.

Comparison of derivatized cyclodextrins and the corresponding cellulose derivatives Because derivatized cellulose and amylose columns are extensively used in our laboratories for both analytical and preparative chromatographic applications, it seemed worthwhile to compare these phases with the corresponding cyclodextrin derivatives. At present only two cellulose phases are commercially available which can be used equally well under reversed-phase and normal phase conditions, namely Chiralcel® OD-R (3,5-dimethylphenyl carbamate and Chiralcel® OJ-R (*para*-methylbenzoate) (Daicel, Japan). We compared these phases with Cyclobond®-DMP and Cyclobond®-PT columns (Advanced Separation Technologies), respectively.

The first experiments were performed under normal phase conditions, using *n*-hexane–2-propanol in a 70–30 ratio as the mobile phase. If products eluted too fast with this mobile phase composition, the amount of 2-propanol was reduced to respectively 20 or 10 vol%. A total of 21 different products were examined. The results of these experiments are summarized in Table 3.

From this data it is clear that for the investigated product classes the cellulose derivatives are far superior compared to the corresponding cyclodextrin phases when normal phase conditions are applied. We thereafter examined the same product series under reversed-phase conditions using a mixture of 70 vol% of methanol and 30% of a 50 mM triethylamine solution adjusted to pH 2.5 with sulfuric acid. The results of these experiments are summarized in Table 4.

When we compare this data with the results obtained under normal phase conditions, we have to conclude that in the reversed phase mode of

Table 3 Derivatized cyclodextrins versus the corresponding cellulose derivatives under normal phase conditions

	Number	%	Number	%	Number	%
Chiralcel OD-R	2	9.5	10	47.6	12	57.1
Cyclobond I-DMP	2	9.5	5	23.8	7	33.3
Chiralcel OJ-R	14 ^b	66.7	–	–	14	66.7
Cyclobond I-PT	–	–	3	14.3	3	14.3

^aFor the partially resolved peaks, the resolution on the cellulose derivatives is always much higher than on the cyclodextrin derivatives.

^bAll products are fully baseline resolved ($\beta = 1.00$).

operation fewer products are separated on the cellulose derivatives, although on the Chiralcel® OJ-R column all separated products are fully baseline resolved. The smallest resolution value equals 2.5 while the largest value is greater than 12.5, while under normal phase conditions the highest resolution value observed equals 6.3.

On the cyclodextrin derivatives a few more products are separated but the increase in number is certainly not spectacular. Furthermore, in many cases where partial resolution has been indicated in the table the chromatograms only showed a small deviation in the peak shape, indicating the early beginning of separation.

For a series of products which under comparable experimental conditions are all very well separated on the native cyclodextrin column, the results on the different cyclodextrin and cellulose derivatives using 50 mM triethylamine adjusted to pH 2.5 with sulfuric acid and methanol in a 30–70 volume ratio as mobile phase are illustrated in Figure 10.

Because only one substance of the test series is separated on the Cyclobond-PT column, and most of the products are only partially resolved on the Cyclobond-DMP column, while all these products are perfectly baseline resolved on native cyclodextrine, it is clear that other parameters must play a role in the chiral recognition process on the derivatized phases.

As a general conclusion it can be stated that for the type of substances investigated the derivatized cyclodextrin columns are, in both modes of operation (normal as well as reversed phase), less universally applicable than the corresponding cellulose derivatives.

Hydroxypropyl- β -Cyclodextrin Derivative

A hydroxypropyl- β -cyclodextrin column (experimental phase of the Chromatography Research group of Merck Darmstadt) in the reversed-phase mode of operation has been extensively investigated. The result on this type of material were completely comparable with the data obtained on the native cyclodextrin columns. However, for the whole range of products the degree of separation was in general

Figure 10 Derivatized cyclodextrin columns versus the corresponding cellulose derivatives. Experimental conditions: column: 250 mm \times 4.6 mm ID (Cyclobond®-DMP, Cyclobond®-PT, Chiralcel® OD-R, Chiralcel® OJ-R); mobile phase: 50 mM triethylamine adjusted to pH 2.5 with sulfuric acid-methanol (30–70, v/v); flow rate: 1 mL min⁻¹.

better on the hydroxypropyl column. To investigate new products, we therefore always start our experiments on a hydroxypropyl- β -cyclodextrin column instead of using the classical native β -cyclodextrin type of material.

γ -Cyclodextrin

A test series of 28 products, which also have been investigated on β -cyclodextrin, have been examined on a γ -cyclodextrin column using a mobile phase consisting of 80 vol% of a 50 mM triethylamine solution in water adjusted to pH 2.5 with sulfuric acid and 20 vol% of methanol. On the β -cyclodextrin column, 22 products were partially or completely resolved. On the γ -derivative only nine products could be resolved.

Compared with the results obtained on the β -cyclodextrin column, it is clear that from a general point of view the γ derivative is less suitable for the separation of the investigated product series. Nevertheless, it remains an additional tool that might help to solve a separation problem when experiments on other types of cyclodextrin columns fail.

Dynamically Generated Cyclodextrin Phases

Instead of using the commercially available chemically bonded cyclodextrin phases, it is also possible to perform enantiomer separations on a reversed-phase column after addition of cyclodextrin or cyclodextrin derivatives to the mobile phase. A number of experiments have been performed with hydroxypropyl- β -cyclodextrin as mobile phase additive. This derivative was initially chosen because it is readily soluble in water.

To investigate the possibilities of a dynamically generated cyclodextrin phase, a test series of 22 products was examined on three different types of reversed-phase packing material. RP Select B (Merck), Hypersil BDS (Shandon) and Aluspher RP Select B (Merck) were selected as stationary phases. An aqueous solution containing 50 mM triethylamine and 50 mM of hydroxypropyl- β -cyclodextrin adjusted to pH 3 with sulfuric acid combined with methanol in an 80–20 volume ratio was used as the mobile phase.

Compared with the data obtained on a chemically bonded hydroxypropyl- β -cyclodextrin column using the same eluent, the chemically bonded column gives, in general, better results than the dynamically coated reversed-phase materials. Furthermore, alumina as stationary phase matrix seems to be less effective. However, in a few exceptional cases the Aluspher Select B column gives as good or even better results than the silica-based materials.

Cyclodextrin Phases in Preparative Chromatographic Applications

The importance of preparative chromatographic enantiomer separations in industry is continuously growing. Therefore it was very interesting to investigate the usefulness of cyclodextrin phases in preparative chromatographic applications.

On an experimental hydroxypropyl- β -cyclodextrin phase (Merck Darmstadt), several products which showed a good resolution on the corresponding analytical material were investigated on a preparative scale. An example of a preparative chromatographic separation is illustrated in Figure 11.

On the hydroxypropyl- β -cyclodextrin phase, in general a loading capacity of 2 mg g^{-1} of packing material was used. However, in some other cases we were able to load up to 4 mg of product per gram of stationary phase, which from a preparative chromatographic point of view certainly can be considered as a reasonable value for this type of application.

Cyclodextrins as Stationary Phases in Gas Chromatography

For the preparation of cyclodextrin-based capillary columns for gas chromatographic applications, two complementary methods have been developed and are commercially used. In the first method, alkylated cyclodextrins are diluted with polysiloxanes and immobilized on the inside wall of a fused silica capillary. In the other method, pentyl and hydroxyalkyldimethylcyclodextrins are coated on the inside wall of a fused silica capillary. Different well-known chromatography companies offer cyclodextrin-based capillary columns:

- Chrompack: diluted cyclodextrins;
- Macherey-Nagel: undiluted n-pentylated or acylated cyclodextrins;
- Advanced Separation Technologies: a broad variety of undiluted cyclodextrin derivatives (permethylated, hydroxypropyl, trifluoroacylated, butyrylated, dialkylated).

Different types of compounds (amines, epoxides, alkanes, alcohols, lactones, sugars, etc.) can be separated on cyclodextrin-based capillary columns.

The usefulness of these materials is illustrated by means of the separation of the four isomers of a piperidine derivative. Gas chromatography on cyclodextrin-based columns was tried after acetylation with trifluoroacetic anhydride using the following procedure:

An advantage of this derivatization procedure was that all types of salts (used to investigate the possibilities of diastereomeric salt formation as a stereoselective synthesis method) could be acylated without prior liberation of the free base.

Figure 11 Preparative chromatographic separation on a β -cyclodextrin columns. Experimental condition: column: 80 mm ID dynamic axial compression column (Prochrom); stationary phase: 500 g 10 μm chemically bonded hydroxypropyl- β -cyclodextrin (experimental phase Merck Darmstadt; packing pressure 80 bar; mobile phase: 50 mM triethylamine adjusted with 50 mM sulfuric acid to pH 2.5–methanol (80–20, v/v); flow rate: 150 mL min⁻¹; detection: UV, wavelength 220 nm, range 2.56 AUFS; sample size: 1 g dissolved in 50 mL of concentrated sulfuric acid; solute:

The first experiments were done on a 15 m \times 0.32 mm ID Chiralsil-Dex[®] column (Chrompack). On this type of column, it was only possible to separate the *cis* and *trans* isomers.

Thereafter, chromatographic experiments were performed on four different cyclodextrin phases from Advanced Separation Technologies:

- ChiralDEX[®] B-PH: (*S*)-2-hydroxypropyl permethylated β -cyclodextrin;
- ChiralDEX[®] B-DA: (2,6-di-*O*-*n*-pentyl)- β -cyclodextrin;
- ChiralDEX[®] B-TA: (2,6-di-*O*-*n*-pentyl-3-*O*-trifluoroacetyl)- β -cyclodextrin;
- ChiralDEX[®] G-TA: (2,6-di-*O*-*n*-pentyl-3-*O*-trifluoroacetyl)- γ -cyclodextrin.

Chromatograms of the different experiments are illustrated in **Figure 12** and **Figure 13**. The largest differentiation between *cis* and *trans* isomers was observed on the permethylated hydroxypropyl- β -cyclodextrin column (ChiralDEX[®] B-PH). However, the best separation of all isomers individually was observed on the trifluoroacetylated β -cyclodextrin column (ChiralDEX[®] B-TA).

Noticeable is the time required to perform an analysis. Compared with the analysis method on the crown ether column, a GC analysis is more than six times faster, although one has to take into account that on the crown ether column the diastereomeric salt could be analysed as such, while for the gas chromatographic method the product has to be derivatized prior to chromatography.

Cyclodextrins in Capillary Electrophoresis

In the pharmaceutical industry the importance of capillary electrophoresis is continuously growing. It is a technique which is increasingly used for determination of the optical purity of intermediates and final products. Many different optically pure compounds

Figure 12 Capillary GC analysis on cyclodextrin stationary phases. Experimental conditions: column: (A) 15 m \times 0.32 mm ID Chiraldex® B-PH ((*S*)-hydroxypropyl- β -cyclodextrin (Astec)); (B) 15 m \times 0.32 mm ID Chiraldex® B-DA (dipentylated β -cyclodextrin (Astec)); carrier gas: helium (linear velocity 25 cm s⁻¹); temperatures: column 150–200°C (3°C min⁻¹), injector 210°C, detector 210°C; detection: FID; injection: 1 μ L split (split ratio 1/100).

can be used to generate the required chiral environment. Cyclodextrins of course are also very suitable as an electrolyte additive.

The different types of cyclodextrins, which are most frequently used are:

- α -cyclodextrin;
- β -cyclodextrin;
- γ -cyclodextrin;
- (2-hydroxy)propylated β -cyclodextrin;
- (2-hydroxy)propylated γ -cyclodextrin;
- Heptakis (2,6-di-*O*-methyl) β -cyclodextrin;
- Heptakis (2,3,6-tri-*O*-methyl) β -cyclodextrin;
- carboxymethylated β -cyclodextrin.

Figure 13 Capillary GC analysis on cyclodextrin stationary phases. Experimental conditions: column: (A) 15 m \times 0.32 mm ID Chiraldex® B-TA (trifluoroacetyl- β -cyclodextrin (Astec)); (B) 15 m \times 0.32 mm ID Chiraldex® G-TA (trifluoroacetyl- γ -cyclodextrin (Astec)); carrier gas: helium (linear velocity 25 cm s⁻¹); temperatures: column 150–200°C (2°C min⁻¹), injector 210°C, detector 210°C; detection: FID; injection: 1 μ L split (split ratio 1/100).

Figure 14 Capillary electrophoresis using a derivatized cyclodextrin as electrolyte additive. Experimental conditions: equipment: P/Ace system 5500 (Beckman); capillary: 50 μm ID uncoated fused silica; total length: 57 cm; length to detector: 50 cm; electrolyte: 20 mM Heptakis (2,3,6-tri-*O*-methyl) β -cyclodextrin 10 mM disodium hydrogen phosphate solution adjusted to pH 2.2 with phosphoric acid; analysis: temperature 25°C, voltage + 20 kV, inject sample 2 s, detection UV (220 nm).

The usefulness of cyclodextrins as an electrolyte additive is illustrated in the following example. A substance containing three optical centres, which means eight possible isomers, had to be separated. HPLC experiments on different types of chiral stationary phases did not succeed in a complete resolution of the mixture. The result of a capillary electrophoresis experiment using Heptakis (2,3,6-tri-*O*-methyl) β -cyclodextrin as electrolyte additive is illustrated in Figure 14.

Compared with HPLC, in capillary electrophoresis many more parameters can be varied to improve separation. Therefore, most of the methods developed on one of the commonly used chiral stationary phases can be replaced by a capillary electrophoresis methods, using cyclodextrins or another chiral auxiliary as electrolyte additive.

Introduction

The separation of enantiomers (optical isomers) by capillary gas chromatography on a chiral stationary

phase (CSP) was discovered by Gil-Av and co-workers at the Weizmann Institute of Science, Israel, in 1966. At the outset of this work, according to Gil-Av,

this topic was in a 'state of frustration'. Nobody believed it could be done. In fact, people were

convinced that there could not possibly be a large enough difference in the interaction between the D- and L-solute with an asymmetric solvent. This was the feeling people had, even those known as unorthodox thinkers. This view had also some experimental basis, because a number of communications had been published, in which it was claimed that such resolutions could be effected, but nobody was able to reproduce these results, and some of them were shown to be definitely wrong.

Today, almost a reversal of this situation exists. According to the *GC Chirbase data bank*, for most volatile racemic compounds of a variety of different chemical classes, ranging from apolar to polar, an appropriate CSP is available and 22 200 chiral separations by gas chromatography (GC) of 7637 analytes on 684 CSPs (120 are commercialized) have been reported up to the end of 1997.

Three principal CSPs are currently employed; these undergo hydrogen bonding, coordination and inclusion. Modified α -, β - and γ -cyclodextrins have proved to be the most versatile and universal CSPs in GC. Anchoring the CSPs to a polysiloxane backbone leads to Chirasil-type stationary phases with improved temperature stability, efficiency and robustness. Immobilization of Chirasil-type stationary phases on the inner column wall furnishes chemically bonded CSPs. Because of the high efficiency, sensitivity and speed, chiral separation by high resolution capillary GC represents a versatile and attractive method for enantiomer analysis. However the prerequisites of the method, i.e. volatility, thermal stability and resolvability of the chiral analytes, restrict its universal use.

The main application of chiral separations by GC is concerned with the precise determination of enantiomeric compositions of chiral research chemicals, intermediates, auxiliaries, metabolites, precursors, drugs, pesticides, fungicides, herbicides, pheromones, flavours and fragrances. As the insight into chirality-activity relationships steadily improves and, as a consequence, legislation on chiral compounds becomes more stringent, the development of reliable methods for the determination of the enantiomeric excess up to 99.9% is of great importance (% enantiomeric excess = $100(R - S)/(R + S)$, where R is the major enantiomer and S the minor enantiomer). This goal is readily met by enantioselective GC.

Methodology

The separation of enantiomers by GC can be performed in two modes.

1. *Indirect method.* Enantiomers are converted off-column into diastereomeric derivatives by chem-

ical reaction with an enantiomerically pure resolving agent and subsequent gas chromatographic separation of the diastereomers is achieved using a conventional achiral stationary phase.

2. *Direct method.* Gas chromatographic separation of the enantiomers is achieved using a chiral stationary phase (CSP) containing a resolving agent of high (but not necessarily 100%) enantiomeric purity.

While the first method entails the formation of diastereomers before separation, the second involves the rapid and reversible diastereomeric association between the CSP (selector) and the racemic, or non-racemic, analyte (selectand). Since diastereomers display different physical properties, discrimination by incomplete recovery, decomposition and losses may occur during work-up, isolation and sample handling in method (1). Also the detector response can be, in principle, different for diastereomers. Because an achiral detection device does not discriminate between enantiomers, the comparison of relative peak areas employing method (2) provides a direct measure of the enantiomeric composition, provided the detector response is linear over a wide concentration range. Consequently, method (2) is preferred for the determination of enantiomeric excess. This approach requires an efficient selector-selectand system displaying chiral recognition.

Enantioselectivity is governed by the biased diastereomeric association between the enantiomers of the selectand and the chiral selector. Fortunately, by employing capillary columns, efficiency is mostly high enough to resolve racemates having a difference of the Gibbs free energy of diastereomeric association as little as $-\Delta_{R,S}(\Delta G) = 0.025 \text{ kJ mol}^{-1}$ (at 25°C), corresponding to a separation factor, α , of 1.01 ($\alpha = k_R/k_S$, with k = the retention factor and the subscript R referring to the second eluted enantiomer and S to the first eluted enantiomer). The measured enantiomeric composition of the analyte determined by method (2) is independent of the enantiomeric purity of the CSP. Lowering the enantiomeric purity of the CSP, however, results in a decrease of α and it is unity when the chiral selector in the stationary phase is racemic. Method (2) is especially useful for the determination of enantiomeric excess when no sample derivatization is required. Owing to the enormous separation power of capillary GC, contaminants and impurities are usually separated from the enantiomers and the simultaneous analysis of the enantiomers of different compounds (e.g. all proteinogenic amino acids) is feasible in one analytical run (cf. Figure 1).

Temperature programming and established ancillary techniques such as multidimensional chromatography

Figure 1 Simultaneous enantiomer separation of 20 proteinogenic amino acids as *N*, *O*, *S*-pentafluoropropanoate-isopropylester (histidine as *N*^m-ethoxycarbonyl) derivatives by GC on Chirasil-Val [IV] between 85 and 185°C at 0.35 bar (gauge) hydrogen. Column, 50 m × 0.27 mm (i.d.) glass capillary. D-Enantiomers are eluted before L-enantiomers. (From Bayer E (1983) Chiral recognition of natural products on optically active polysiloxanes. *Zeitschrift für Naturforschung* 38b: 1281–1291.)

and the use of interfacing and coupling methods can readily be adapted to chiral separations. Sensitivity can be extended to the picogram level by electron capture detection or by the combination of gas chromatography with mass spectrometry (GC-MS). GC-MS-selected ion monitoring (SIM) can detect trace amounts of enantiomers in complex matrices.

When the racemate is highly volatile and the chiral separation factor is large ($\alpha > 1.3$), preparative enantiomer separation by GC with packed columns is possible. The development of simulated moving bed (SMB) approaches can be expected in the future. Semipreparative separations can already be carried out at low α values. Recovery from the gaseous carrier is straightforward and pure enantiomers can be obtained even on enantiomerically impure CSPs. For analytical purposes it may be important to differentiate a separation of a chiral compound into enantiomers from the common separation of two achiral analytes. A racemate, when resolved, should produce an exact 1 : 1 peak ratio of the enantiomers. Clearly, only one peak (peak coalescence, $\alpha = 1$) is expected when the racemic CSP is employed. When two CSPs of opposite configurations are applied in different columns, peak inversion (peak switching) can be observed for a chiral analyte in which one enantiomer is in excess.

Classification of Chiral Stationary Phases

Enantiomer separation by GC is mainly performed on three types of CSPs:

- chiral amino acid derivatives via hydrogen bonding;

- chiral metal chelates via coordination (complexation GC);
- cyclodextrin derivatives via inclusion.

Initially, the chiral selectors were used as involatile neat liquids or as solutions in squalane or polysiloxanes, respectively. Subsequently, a number of chiral selectors have been chemically linked to polysiloxanes (Chirasil-type stationary phases).

Chiral Stationary Phases Based on Hydrogen Bonding

The first successful separation of racemic *N*-trifluoroacetyl amino acid alkyl esters on glass capillary columns coated with involatile *N*-trifluoroacetyl-L-isoleucine lauryl ester [I] (cf. **Scheme 1**) was achieved by Gil-Av and co-workers in 1966 and a semipreparative version of this method was reported later. Since then the great potential of this fundamental approach has stimulated continuing research on enantiomer separation not only by GC, but also by other chromatographic techniques such as HPLC.

It was recognized that in the dipeptide phase [II] (cf. **Scheme 1**) the C-terminal amino acid was not essential to chiral recognition while the additional amide function was important for additional hydrogen bonding. The second chiral centre was therefore sacrificed by preparing the diamide [III], e.g. derived from valine. This chiral selector was subsequently coupled via the amino function to a statistical copolymer of dimethylsiloxane and (2-carboxypropyl)methylsiloxane. The resulting polymeric CSP, Chirasil-Val [IV], combining enantioselectivity and efficiency of silicones, exhibits excellent GC properties for the enantiomer separation of chiral compounds undergoing hydrogen bonding. Chirasil-Val [IV] is commercially available in both enantiomeric

Scheme 1 Hydrogen-bonding-type chiral stationary phases.

forms. The temperature-programmed simultaneous enantiomer separation of all proteinogenic amino acids in less than 25 min is illustrated in Figure 1. A straightforward approach to polymeric CSPs is based on the modification of cyanoalkyl-substituted polysiloxanes (XE-60, OV-225). For instance the diamide **[III]** was chemically linked to the polysiloxane to give (L)-**[V]**. The diastereomeric selectors (L, R, and L, S)-**[VI]** contain two chiral centres that enhance enantioselectivity (matched case) or compensate enantioselectivity (mismatched case).

Enantiomer separation by hydrogen-bonding CSPs generally requires derivatization of the analyte in order to increase volatility and/or to introduce suitable functions for additional hydrogen-bonding association.

Chiral Stationary Phases Based on Coordination

The chiral metal coordination compound dicarbonyl-rhodium(I)-3-trifluoroacetyl-(1*R*)-camphorate **[VII]** (cf. **Scheme 2**) was used for the enantiomeric separation of the chiral olefin 3-methylcyclopentene by complexation GC in 1977. The scope of enantiomer separation by complexation GC was later extended to oxygen-, nitrogen- and sulfur-functionalized compounds using chiral ketoenolate-*bis*-chelates of, among others, manganese(II) and nickel(II) ions derived from terpene ketones such as camphor **[VIII, IX]**, menthone, carvone, pulegone, and others after perfluoroacylation.

Figure 2 illustrates the enantiomer separation by complexation GC of simple aliphatic oxiranes,

belonging to the smallest chiral molecules. A limiting factor of coordination-type CSPs **[VIII, IX]** is the low temperature range of operation (25–120°C). The thermal stability has been increased by the

Scheme 2 Coordination-type chiral stationary phases.

Figure 2 Enantiomer separation of monoalkyl-substituted oxiranes by complexation GC on manganese (II) bis[3-(heptafluorobutanoyl)-(1*R*)-camphorate] [IX] (0.05 molal in squalane) at 60°C. preparation of immobilized polymeric CSPs (Chirasil-Metal; [X] in Scheme 2). In Figure 3 the GC enantiomer separation of homofuran at 95°C on Chirasil-Nickel [X] is shown.

Chiral Stationary Phases Based on Inclusion

The first enantiomer separation using an inclusion-type CSP in GC was reported in 1983 for α - and β -pinene and *cis*- and *trans*-pinane on packed columns containing native α -cyclodextrin in formamide. Later it was recognized that alkylated cyclodextrins

(CDs) can be employed in high resolution capillary columns for enantiomer analysis. Thus, neat permethylated β -cyclodextrin, [XI] (cf. Scheme 3), was used above its melting point and in a supercooled state. Per-*n*-pentylated and 3-acyl-2,6-*n*-pentylated CDs are liquids at room temperature. The CD derivatives, [XIII]–[XVII], have been used in the undiluted form for the separation of enantiomers of many classes of compounds on deactivated Pyrex glass capillary columns. The more polar CD derivatives, [XX]–[XXIII], have been coated on fused silica capillary columns.

To combine the enantioselectivity of CDs with the excellent coating properties and efficiency of polysiloxanes, alkylated CDs have been preferentially dissolved in moderately polar polysiloxanes (silicones) such as OV-1701. Thus, the CD derivatives can be employed for GC enantiomer separation irrespective of their melting point and phase transitions. The simultaneous separation of a test mixture of enantiomers of different classes of compounds is depicted in Figure 4.

The presence of three hydroxyl groups that can be regioselectively alkylated and acylated offers an enormous number of possible α -, β - and γ -cyclodextrin derivatives, which are not always readily accessible and may require tedious purification steps. Occasionally, CD derivatives such as octakis(3-*O*-butanoyl-2,6-di-*O*-*n*-pentyl)- γ -cyclodextrin [XVII] are highly enantioselective for the GC enantiomer

separation of certain racemates (cf. Figure 5). Also derivatives containing the bulky butyldimethylsilyl substituent at the lower rim of the CD ([XVIII] and [XIX]) represent useful complementary CSPs.

A superior class of CSP has been obtained by chemically linking the CD derivatives to the polysiloxane backbone furnishing Chirasil-Dex [XXIV] (cf. Scheme 4).

Fused silica columns coated with Chirasil-Dex have advantages such as:

- use of a nonpolar polysiloxane matrix (in which CD derivatives cannot be physically diluted) resulting in low elution temperatures for polar analytes;
- high degree of inertness allowing analysis of polar compounds without prior derivatization;
- higher CD concentration resulting in increased separation factors;

Figure 4 Enantiomer separation of the test mixture α -pinene (1, 2), *trans*-pinane (3, 4), *cis*-pinane (5, 6), 2,3-butanediol (rac) (7, 8), 2,3-butanediol (*meso*) (9), γ -valerolactone (10, 11), 1-phenylethylamine (12, 13), 1-phenylethanol (14, 15) and 2-ethylhexanoic acid (16, 17) by GC on heptakis(2,3,6-tri-*O*-methyl)- β -cyclodextrin [XI] (10% (w/w) in OV-1701) at 50°C and 0.7 bar (gauge) helium. - long-term stability with absence of droplet formation leading to loss of efficiency;
- immobilization by crosslinking and/or surface bonding;
- compatibility with all injection techniques.

The rationalization of chiral recognition involving CD derivatives is difficult since almost all classes of chiral compounds, ranging from apolar to highly polar, are susceptible to enantiomer separation on a certain CD-derived CSP, often with no logical dependence on molecular shape, size and functionalities of the selectand and the selector (α , β , γ). Clearly, multimodal recognition processes are important which

Figure 5 Enantiomer separation of the inhalation anaesthetics desflurane, isoflurane and enflurane by GC on immobilized polysiloxane-bonded octakis(3-*O*-butanoyl-2,6-di-*O*-*n*-pentyl)- γ -cyclodextrin [XVIII] at 28°C. Scheme 4 Chirasil-Dex-type chiral stationary phase.

may involve inclusion, hydrogen bonding, dipole-dipole interactions and dispersion forces. Since enantiomer separations have also been observed with per-*n*-pentylated amylose, inclusion may not be a prerequisite for chiral recognition using CDs. Mechanistic investigations, some of which include molecular modelling studies, have been carried out although no clear-cut rationale for chiral recognition has emerged thus far.

Thermodynamics of Enantiomer Separation

Enantiomer separation by GC is brought about by the difference in the Gibbs free energy $-\Delta_{R,S}(\Delta G)$ of the diastereomeric association equilibria between the enantiomers (selectand) and the CSP (selector). An important prerequisite is a fast and reversible association equilibrium (fast kinetics). The chemical association equilibria in the stationary phase are described by K_R and K_S , with R referring to the second eluted enantiomer and S to the first eluted enantiomer. For enantiomer separation, the Gibbs-Helmholtz equation [1] applies, where R is the universal gas constant, T is the temperature (K), H is the enthalpy and S is the entropy.

$$-\Delta_{R,S}(\Delta G) = RT \ln \frac{K_R}{K_S} = -\Delta_{R,S}(\Delta H) + T \Delta_{R,S}(\Delta S) \quad [1]$$

For a 1:1 molecular association, the quantities $\Delta_{R,S}(\Delta S)$ and $\Delta_{R,S}(\Delta H)$ display an opposing effect on $-\Delta_{R,S}(\Delta G)$. At the isoenantioselective temperature T_{iso} , given by eqn [2], peak coalescence (second kind) occurs ($\Delta_{R,S}(\Delta G) = 0$, $K_R = K_S$; no enantiomer separation).

$$T_{iso} = \frac{\Delta_{R,S}(\Delta H)}{\Delta_{R,S}(\Delta S)} \quad [2]$$

Above T_{iso} the sign of enantioselectivity changes, leading to peak inversion (second kind). Below the coalescence temperature, the sign of enantioselectivity $\Delta_{R,S}(\Delta G)$ is governed by $-\Delta_{R,S}(\Delta H)$ and above it, by $\Delta_{R,S}(\Delta S)$. A rare example of the temperature-dependent reversal of enantioselectivity in GC enantiomer separation on a single CSP is demonstrated in Figure 6. Usually, even at high temperatures, enantioselectivity is dominated by enthalpy control and separation factors increase with decreasing temperature. Therefore, it is recommended that the lowest possible temperature is used for enantiomer separation by GC.

For undiluted CSPs the quantity $-\Delta_{R,S}(\Delta G)$ can easily be obtained from the separation factor α_{undil} ,

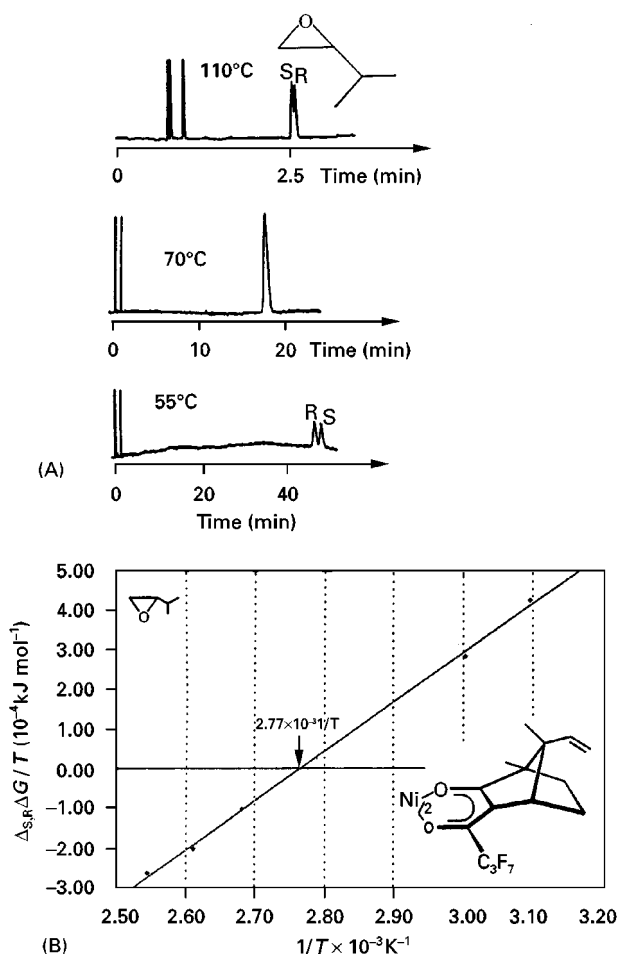

Figure 6 (A) Temperature-dependent peak inversion (second kind) at 55 and 110°C and peak coalescence (second kind) at 70°C during GC enantiomer separation of isopropylloxirane on nickel (II) bis[3-(heptafluorobutanoyl)-(1*R*)-8-methylene-camphorate] (a derivative of [IX]) (0.126 molal in OV-101). Column, 22 m × 0.25 mm (i.d.) glass capillary. (B) Linear van't Hoff plot and determination of T_{iso} . (From Schurig V (1997) In: Jinno K (ed.) *Chromatographic Separations Based on Molecular Recognition*, ch. 7, pp. 371–418. New York: Wiley-VCH.)

according to eqn [3].

$$-\Delta_{R,S}(\Delta G) = RT \ln \alpha_{\text{undil}} \quad [3]$$

Although it is occasionally used, eqn [3] is not valid for diluted CSPs because α_{dil} is concentration dependent.

Enantiomerization

The configurational integrity of the enantiomers during the GC process of separation is essential for a correct enantiomer analysis. When enantiomers invert the configuration (or conformation) during separation, transient elution profiles are obtained that are characterized by plateau formation between the terminal peaks of the enantiomers. The barrier of enantiomerization (ΔG^\ddagger) can be determined by dynamic GC via peak form analysis of interconversion profiles and the comparison of experimental and simulated chromatograms (cf. Figure 2). Only minute amounts of the easily available racemic compound are required. If enantiomerization is fast within the chromatographic timescale, peak coalescence (third kind) occurs (cf. Figure 2 at 130°C).

Another on-column method for determining interconversion kinetics is based on the 'stopped-flow' technique. In the first part of the column enantiomers are quantitatively separated. Afterwards, the flow is stopped and the column is heated, whereby enantiomerization in the separated fractions commences. After cooling, the flow is restored and the enantiomerized fractions are separated in the second part of the column. From the reaction time and enantiomeric compositions the rate constant can be calculated. Using a combination of three columns, i.e. a separation column, an empty reactor column and another separation column, connected via switching valves for peak-cutting, enantiomerization can be carried out in the gas phase and in the absence of the CSP in the reactor column (enantioselective multidimensional stopped-flow GC).

Assignment of Absolute Configurations by Enantioselective GC

The determination of absolute configurations of chiral analytes is an important task in enantiomer analysis. Absolute configurations of minute amounts of chiral samples may be determined directly, and free of chiroptical evidence, by GC via co-injection of reference compounds with known stereochemistry. Absolute configurations may also be predicted indirectly by empirical rules that correlate the absolute

configuration and the order of elution for enantiomers belonging to homologous series of compounds. Although consistent relationships between the order of elution and absolute configuration of congeners have been observed in many instances, remarkable inconsistencies are also known. As a rule, such comparisons, if any, should be restricted to measurements at the same temperature since peak inversion (second kind) may occur at different temperatures as the result of enthalpy versus entropy compensation or multimodal chiral recognition mechanisms. Therefore, the assignment of absolute configurations by GC can be ambiguous.

Method of Enantiomer Labelling

Enantiomers can be quantified in complex matrices when a known amount of the pure enantiomer is added as an internal standard. The pure enantiomer is an ideal internal standard as the enantiomeric excess is not influenced by sample manipulations in diluted systems (achiral derivatization, dilution, injection, detection, chemical and physical losses). The method of enantiomer labelling presupposes the precise knowledge of the enantiomeric excess of the sample and the standards.

Simultaneous enantiomer and isotopic labelling in enantiomer analysis can also be carried in the GC-MS-SIM mode.

Precision and Sources of Error

The precision of enantiomeric excess determined by GC is high over the whole range from 0 (racemic) to 99.9% (nearly enantiomerically pure). At a high enantiomeric excess, the minor enantiomer should preferentially elute as the first peak in order to facilitate correct integration.

Despite the great success of GC for determining enantiomeric excess, potential sources of error should be considered:

- decomposition of the sample during chromatography (the enantiomer which spends a longer time in the column will be lost preferentially, causing an error in enantiomeric excess);
- coelution of impurities accidentally increasing peak areas;
- enantiomerization causing peak distortions (plateau formation);
- peak distortions caused by inadequate instrumentation;
- nonlinear detector response.

In general, the error in enantiomeric excess due to decomposition of the analyte can be reduced if the

difference of the residence time in the column is minimized for both enantiomers. This goal may be realized by using short columns, high pressure drops, elevated temperatures and CSPs exhibiting only small separation factors α . A rather frequent cause for the deviation from the expected 1:1 ratio for the racemic mixture consists of the coelution of impurities. This interference can be recognized by determining the enantiomeric excess on two columns coated with CSPs of opposite chirality. The verification of the ideal 1:1 ratio of a racemic mixture is always recommended in enantiomer analysis by chromatography. It may also be used to test integration devices.

Practical Considerations

The merit of GC enantiomer separation is the great range of resolvable classes of compounds. With a few exceptions, enantiomer separation by GC is characterized by low separation factors α , and, as a (beneficial) consequence, reduced separation times. The use of highly efficient capillary columns is recommended. Chirasil-Val [IV], Chirasil-Dex [XXIV], and most cyclodextrin derivatives, [XI]–[XXIII], coated onto fused silica capillary columns, are commercially available. Factors such as availability, price, performance and reproducibility should guide the analyst when selecting chiral stationary phases for GC. Immobilized chiral stationary phases, such as Chirasil-Dex [XXIV], have the advantage of solvent compatibility, resistance to temperature shock and longevity. Enantiomer separation on Chirasil-type stationary phases can be performed in the usual temperature range 25–220°C. For special applications it is also possible to use cryogenic temperatures down to –20°C.

The dimensions of commercial columns are typically 10–25 m \times 0.25 mm (i.d.) and the film thickness of the chiral stationary phase is 0.25 μ m. Column miniaturization has important merits. Since enantiomer separation represents a binary separation system, the whole elution window required for multi-component mixtures need not be exploited unless enantiomers are detected in complex matrices. With shorter columns, the elution temperature can be decreased, so that the chiral separation factor α is increased in the common enthalpy-controlled region of enantioselectivity. The loss of efficiency is compensated by the gain of selectivity leading to comparable resolution factors R_s . The shorter analysis times increase the sharpness of peaks and hence the detectability of the enantiomers. Recommended are 2 m \times 0.25 mm (i.d.) columns with a film thickness of 0.25 μ m. Further miniaturization via reduction of the

internal diameter of the columns to 0.1 and 0.05 mm (i.d.) requires thinner films of the stationary phase in order to keep the phase ratio constant. The reduced amount of stationary phase decreases the sample capacity. The reduced signal-to-noise ratio may become critical in regard to the precision of the enantiomeric excess determination.

Unfortunately, there is no universal CSP available and column selection is a matter of trial and error. Chirasil-Val [IV], Chirasil-Dex [XXIV] and permethylated β -cyclodextrin dissolved in polysiloxane [XI] represent the most popular CSPs. On a given enantioselective column, the parameters column length, temperature, film thickness, concentration of CSP, mobile phase velocity and their influences on the resolution factor R_s (which is governed by the retention factor k , separation factor α and efficiency N) have to be carefully balanced. Some variables cannot be freely selected when commercial columns are used.

While Chirasil-Val [IV] and Chirasil-Metal [X] are available in both enantiomeric forms, Chirasil-Dex [XXIV] and other modified cyclodextrins, [XI]–[XXIII], occur only in the D form. The strategy of peak inversion (first kind), employed to elute the minor enantiomer as the first peak, is precluded with carbohydrate-based CSPs.

Ion-Pair Chromatography

E. Hedin, Uppsala University, Uppsala, Sweden

Copyright © 2000 Academic Press

Introduction

In ion pair chromatography, the solute ion is distributed between the mobile and the stationary phase together with an ion of opposite charge (a so-called counterion). The technique is often used in reversed-phase chromatography as a convenient method to control the retention of solutes. The principle may, for example, be applied to direct chiral separations using either chiral or achiral counterions. When using an achiral counterion, the chromatographic system has to contain a chiral selector, e.g., a chiral stationary phase. The purpose of an achiral counterion then is to control the retention of the solute. However, the counterion may also influence the stereoselectivity by interactions with the chiral selector molecules. A chiral counterion may, on the other hand, be used with non-chiral stationary phases to promote chiral separation.

Ion Pairs: Principles

In order to distribute the solute molecules in a nonpolar environment, it has to be uncharged. However, if an ion of opposite charge is present in enough concentration the two ions may be distributed as a pair in the same way. An ion being double charged may be distributed together with two ions of single charge or one double charged, the only prerequisite being electroneutrality of the pair (Figure 1).

The equilibrium for a simple 1:1 ion pair may be given as:

and is characterized by an extraction constant:

$$K_{\text{ex}} = \frac{[\text{HBC}]_{\text{org}}}{[\text{HB}^+]_{\text{aq}} \times [\text{C}^-]_{\text{aq}}} \quad [1]$$

The nonpolar environment may be a liquid (mobile or stationary), a surface or a micelle in the liquid. For simplicity the principle for a liquid–liquid chromatographic system with aqueous mobile phase will be presented. Here the retention factor for the solute, k_{HB^+} , is equal to:

$$k_{\text{HB}^+} = D_{\text{HB}^+} \times (V_s/V_m) \quad [2]$$

where D_{HB^+} is the distribution coefficient of the solute between the aqueous mobile phase and the organic stationary phase and V_s and V_m are the volumes of the two phases.

The distribution coefficient is defined as:

$$D = \frac{C_{\text{org}}}{C_{\text{aq}}} \quad [3]$$

i.e., the ratio of the total concentration of solute in organic phase over the total concentration in aqueous phase. For the ion pair, D_{HB^+} may be expressed as:

$$D_{\text{HB}^+} = \frac{[\text{HBC}]_{\text{org}}}{[\text{HB}^+]_{\text{aq}}} = K_{\text{ex}} \times [\text{C}^-]_{\text{aq}} \quad [4]$$

Thus, the retention factor will depend on the extraction constant of the ion pair and the concentration of counterion in the aqueous mobile phase. The magnitude of the extraction constants depends on the hydrophobicity of the solute and the counterion, the

Figure 1 Distribution of charged compounds to a nonpolar phase together with a counterion.

kind of interaction forces between the two ions, and the physiochemical properties of the organic phase.

For protolytic solutes, the retention will also depend on the pH of the aqueous phase, as the charge of the solute is pH dependent. At a pH where an amine is uncharged, its distribution coefficient is:

$$D_B = \frac{[B]_{\text{org}}}{[B]_{\text{aq}}} = K_{D(B)} \quad [5]$$

where $K_{D(B)}$ is the distribution constant of B.

Considering a more general expression for the distribution coefficient for a basic compound over the entire pH range in the presence of a counterion, the equation is as follows:

$$D = \frac{C_{\text{org}}}{C_{\text{aq}}} = \frac{[B]_{\text{org}} + [\text{HBC}]_{\text{org}}}{[B]_{\text{aq}} + [\text{HB}^+]_{\text{aq}}} \\ = \frac{K_{D(B)}K'_{(\text{HB}^+)}}{K'_{(\text{HB}^+)} + a_{\text{H}^+}} + \frac{K_{\text{ex}(\text{HBX})}[\text{C}^-]_{\text{aq}}a_{\text{H}^+}}{K'_{(\text{HB}^+)} + a_{\text{H}^+}} \quad [6]$$

Uncharged form Ion pair

where $K'_{(\text{HB}^+)}$ is the acid dissociation constant of HB^+ defined as:

$$K'_{[\text{HB}^+]} = \frac{[\text{B}] \cdot a_{\text{H}^+}}{[\text{HB}^+]} \quad [7]$$

Equation [6] means that the retention of a solute may be made up of two parts: the retention as an ion pair and the retention in an uncharged form:

$$k = k_{\text{uncharged}} + k_{\text{ion pair}} \quad [8]$$

In chromatographic systems with solid stationary phases, the retention involves distribution with a solid surface. The limited capacity of the surface and the possibility to have competition for the limited adsorption sites have to be considered in the equation

but the models otherwise resemble each other to a large extent.

Principles of Chiral Separation Using Achiral Counterions

The achiral counterion itself does not provide stereochemical interactions and thus it is expected to only influence the retention and not the separation of an enantiomeric pair. Different counterions have been added to the aqueous mobile phase in a liquid-liquid chromatographic system with a nonpolar chiral stationary phase (a tartaric acid ester). The enantioselectivity was about the same for all counterions studied and, as expected, the type of ion and its concentration could be used to control the retention (Table 1).

Several of the chiral selectors used are, however, complex biomolecules, e.g., proteins which cannot be treated as simple organic phases. The addition of charged (and uncharged) compounds to the mobile phase, when a protein is used as the stationary phase, may change both the retention and the enantioselectivity. The changes in enantioselectivity may be dramatic; the two enantiomers in a pair may even elute in an opposite order.

Principles of Chiral Separation Using Chiral Counterions

The chiral counterion may be the only chiral compound needed for separation of enantiomers in a chromatographic system. The solute enantiomers form diastereomeric ion pairs with the chiral counterion, also called the selector (Figure 2). In order to achieve enantioselectivity, the ion pairs formed should have different stabilities and/or different distribution properties with the stationary phase. If the difference in distribution properties with the stationary phase is responsible for the stereoselectivity, it is important that the retention as a diastereomeric ion pair (k_{chiral}) is more pronounced than the retention of

Table 1 Influence of counterion structure on retention and enantioselectivity

Solute	—		ClO_4^- (45 mM)		PF_6^- (45 mM)		Heptane SO_3^- (45 mM)		Hexane SO_3^- (45 mM)		Hexane SO_3^- (90 mM)	
	α	k	α	k	α	k	α	k	α	k	α	k
N-methylephedrine	1.14	1.1	1.13	2.2	1.13	4.6	1.11	7.3	1.12	3.4	1.10	6.2
Ephedrine	1.15	1.1	1.15	2.2	1.15	4.0	1.13	7.7	1.41	3.4	1.13	6.9
Norephedrine	1.16	1.2	1.16	2.5	1.16	4.2	1.14	9.6	1.15	4.1	1.14	8.6

Solid phase: Novapak Phenyl (4 μm -particles); liquid stationary phase, (2*R*,3*R*)-di-*n*-butyltartrate; mobile phase, counterion in phosphate buffer pH 2.8 (ionic strength 0.1). PF_6^- = hexafluorophosphate, Heptane SO_3^- = heptanesulfonate, Hexane SO_3^- = hexanesulfonate.

Figure 2 Ion pair formation in mobile phase and possible distribution to stationary phase.

the solute alone (k_{achiral}) (Figures 2 and 3). Referring to eqn [8] the retention factor may be described as:

$$k = k_{\text{achiral}} + k_{\text{chiral}} \quad [9]$$

and the observed α value ($\alpha_{R/S}$) compared to the maximal α (only chiral retention) as:

$$\alpha_{R/S} = \frac{k_R}{k_S} = \frac{\alpha_{\text{max}} + (k_{\text{achiral}}/k_{S(\text{chiral})})}{1 + (k_{\text{achiral}}/k_{S(\text{chiral})})} \quad [10]$$

where the *S*-form is eluted first. Therefore, the concentration of selector has to reach a certain level to assure maximal stereoselectivities (α values).

In order to promote the formation of an ion pair in the mobile phase, solvents of low polarity have often been used, e.g., hexane and dichloromethane. The retention and stereoselectivity is controlled by the temperature, the mobile phase composition (i.e. type and concentration of counterion, competing substances and polar modifiers) as well as the choice of stationary phase.

The chiral counterion and its concentration influences the equilibria outlined in Figure 2. Equation [11] expresses the stereoselectivity when varying the counterion concentration. From eqn [11] it is obvious that the influence of selector concentration on enantioselectivity is difficult to predict. The effect of a changed selector concentration will depend on the relative magnitudes of ion pair formation constants in the mobile phase and stereoselective distribution to the stationary phase:

$$\alpha_{S/R} = \frac{(K_1 + K_1 K_{RR} [(R)\text{-Selector}]_{\text{mob}} + K_{SR} K_{SR}^* [(R)\text{-Selector}]_{\text{mob}} + K_{SR} K_{RR} K_{SR}^* [(R)\text{-Selector}]_{\text{mob}}^2)}{(K_1 + K_1 K_{SR} [(R)\text{-Selector}]_{\text{mob}} + K_{RR} K_{RR}^* [(R)\text{-Selector}]_{\text{mob}} + K_{SR} K_{RR} K_{RR}^* [(R)\text{-Selector}]_{\text{mob}}^2)} \quad [11]$$

K_1 = adsorption constant for achiral adsorption of solute.

K_{RR} = formation constant of (R)-Solute : (R)-Selector in mobile phase.

K_{SR} = formation constant of (S)-Solute : (R)-Selector in mobile phase.

K_{RR}^* = adsorption constant of the diastereomeric ion pair (R)-Solute : (R)-Selector.

K_{SR}^* = adsorption constant of the diastereomeric ion pair (S)-Solute : (R)-Selector.

$[(R)\text{-Selector}]_{\text{mob}}$ = concentration of chiral selector in the mobile phase.

The chiral selector does not have to be optically pure, as the interactions are noncovalent. An enantiomerically impure selector will affect the stereoselectivity but only an impurity of exactly 50% may ruin it completely. The expected stereoselectivity, $\alpha_{S/R}^*$ when using enantiomerically impure selectors in the mobile phase may be calculated from the following expression:

$$\begin{aligned} \alpha_{S/R}^* &= \frac{\alpha_{S/R} [(R)\text{-Selector}]_{\text{mob}} + [(S)\text{-Selector}]_{\text{mob}}}{[(R)\text{-Selector}]_{\text{mob}} + \alpha_{S/R} [(S)\text{-Selector}]_{\text{mob}}} \\ &= \frac{\alpha_{S/R} P + [100 - P]_{\text{mob}}}{P + \alpha_{S/R} [100 - P]_{\text{mob}}} \end{aligned} \quad [12]$$

where $\alpha_{S/R}$ is the stereoselectivity obtained when the selector is present in one pure enantiomeric form (here the *R*-form) and *P* is the fraction of selector present in the *R*-form. Experiments have shown good agreement with theory (Table 2).

Chiral Counterions Used

In order to obtain chiral discrimination of the solutes, the counterion and solute ions have to establish

multipoint interactions where the stability of the interactions differ between the enantiomers. For the stability of the diastereomeric ion pair, it is advantageous if the molecules involved have a rigid structure, and most of the chiral counterions used are rigid. At least three points of interaction for one of the

Figure 3 Influence of achiral retention on the separation factor for the enantiomers. (Reprinted from Heldin E. (1991) Tartaric acid derivatives as chiral selectors in liquid chromatography. *Comprehensive Summaries of Uppsala Dissertations from the Faculty of Pharmacy* 74: 1–37, with permission from Acta Universitatis Upsaliensis.)

enantiomers are necessary for recognition of the three-dimensional structure. All these points do not, however, have to be only between selector and solute but may also involve solvent molecules and the achiral packing material.

Most of the early studies with chiral ion-pairing selectors in the mobile phase were performed with a silica-based DIOL stationary phase. The DIOL functionality was chosen after comparing several phases (nitrile, nitro, C2, silica) as it gave the most

symmetrical peaks. Uncoated silica has in some cases been used for the purpose of retaining hydrophilic compounds. As the solid phase, i.e., the particle surface, plays an important role in the chiral recognition process it should be considered in the optimization process. The introduction of porous graphitic carbon (PGC) as packing material thus opened new possibilities and has broadened the use of chiral mobile phase additives. PGC is a very hydrophobic material whose unique three-dimensional structure is suitable for the recognition of isomers. Another advantage is that it may be used with more polar mobile phases, e.g., methanol–water mixtures. The use of polar mobile phases has several advantages in the separation process, among them the possibility of direct injection of biological fluids.

(+)-10-Camphorsulfonic Acid and Analogues

(+)-10-Camphorsulfonic acid [I] has been used to separate the enantiomers of amino alcohols, mainly β -blocking agents (derivatives of 1-aryl-2-amino alcohols). These solutes have an aromatic part to which a side chain is connected. The selectivity has been found to be dependent on the distance between the hydroxyl and the amine groups, implying that both these structural features play an important role in chiral recognition. (+)-10-Camphorsulfonic acid is an aprotic acid and it also contains an oxo group which may take part in hydrogen bonding. A model for the interaction between (+)-10-camphorsulfonic acid and β -blocking agents has been suggested and is shown in **Figure 4**. Several chiral separations have been performed using (+)-10-camphorsulfonic acid in dichloromethane: 1-pentanol (199:1) as mobile phase and a DIOL stationary phase. When using a DIOL functionalized packing material and sulfonic acid in the mobile phase, it is of vital importance to choose a solvent with a low content of polar components as the mobile phase in order to promote ion pair

Figure 4 Model for interaction between the (+)-10-camphorsulfonic acid and amino alcohols. (Reprinted from Pettersson C and Schill G (1986) Separation of enantiomers in ion-pair chromatographic systems. *Journal of Liquid Chromatography* 9: 269–290, by courtesy of Marcel Dekker, Inc.)

formation. Attempts to use Br-3-(+)-10-camphorsulfonic acid in a system with a DIOL stationary phase, in order to separate β -blocking agents, have not been successful. With these solutes and in that particular system, the Br group was believed to sterically prevent the three-point contact between the selector and the solute. Moving the sulfonate group away from the oxy group to position 8 (Br-3-(+)-8-camphorsulfonic acid) restored the stereoselectivity to some extent.

	R ₁	R ₂	R ₃
(+)-10-Camphorsulfonic acid	SO ₃ H	H	H
(+)-3-Br-10-Camphorsulfonic acid	SO ₃ H	H	Br
(+)-3-Br-8-Camphorsulfonic acid	H	SO ₃ H	Br

The selector has been used in a system with porous graphitic carbon (PGC) as support in order to separate some dihydropyridines. The enantiomers of amlodipine and an analogue, UK52.829, were separated

with a mobile phase consisting of 5×10^{-3} M (+)-10-camphorsulfonic acid in dichloromethane : methanol (25 : 75) (Figure 5). As stated above, PGC may be used together with polar mobile phases. A fairly high content of dichloromethane is needed in order to elute the dihydropyridines from the highly retentive surface of PGC. Exchanging (+)-10-camphorsulfonic acid for Br-3-(+)-10-camphorsulfonic acid still separated the enantiomers although with somewhat lower selectivities.

Cinchona Alkaloids

The cinchona alkaloids are rigid molecules containing four chiral carbons [II] and their use as chiral selectors have been studied. Quinine has the absolute configuration 3(*R*),4(*S*),8(*S*),9(*R*) while quinidine has 3(*R*),4(*S*),8(*R*),9(*S*). It is at the positions 8 and 9 that the chiral recognition is believed to take place due to hydrogen bonding groups, and the exchange of quinine for quinidine reverses the retention order of some enantiomers, e.g., 10-camphorsulfonic acid and O-methylmandelic acid (Table 3). The mechanism of chiral recognition is, however, not simple as the effect of an exchange of the hydroxyl for an ethylcarbonate group at position 9 reduces the enantioselectivities but not to the same extent for all solutes. Furthermore, the exchange of an ethoxy group for hydrogen at the aromatic moiety (cinchonidine) also had an influence on the stereoselectivity. The results in

^bRetention order uncertain.

Table 3 come from two different mobile phases. Stereoselectivities should be comparable, as n-hexane does not have a significant effect on enantioselectivity. A high content of n-hexane is needed to retain hydrophilic compounds.

The complexity of the systems is high as the solutes may form ion pairs in the mobile phase, as well as be distributed to the stationary phase both as ion pairs and as uncharged compounds (see Figure 2). In addition, the selectors may be distributed to the stationary phase alone or together with mobile phase ions. In the cinchona systems, the mobile phase often contains an acid to control the retention and the stereoselectivity of the acidic solutes. It is not possible to provide a simple guideline to know which acid to use as the effect on enantioselectivity differs between the solutes studied. The distribution to the packing material is important and influences both the retention and the enantioselectivity.

When optimizing chiral ion pair separations it is therefore important to carefully consider both the mobile phase and the packing material. Enantiomers of *N*-blocked amino acids, sulfonic acids and carboxylic acids have been separated with the cinchona alkaloids as mobile phase additives. An example of

the resolution of D- and L-dansyl-valine is shown in Figure 6.

Peptides

The first peptide used for a chiral separation was L-leucine-L-leucine-L-leucine, a zwitterionic compound. Some amino acids, including, D,L-tryptophan and glycyl-D,L-phenylalanine, have been partially resolved by reversed-phase chromatography. The *N*-protected dipeptide *N*-benzyloxycarbonyl-glycyl-L-proline (L-ZGP), shown in Table 4, has been used successfully as a counterion in the separation of enantiomers of amines. When bare silica or modified silicas are used as packing material, an enantiomeric pair generally has to be a β -amino alcohol in order to be separable. In order to separate the enantiomers of amines (which lack a strong hydrogen-bonding group in the vicinity of the asymmetric carbon atom) or rather hydrophilic amino alcohols, PGC is a good choice of stationary phase. Most recent separations have been performed on PGC material and a large number of different enantiomers have been shown to be separable, of which some examples are given in Table 5. The influence of the structure of the chiral selector on the enantioselectivity of alprenolol has been studied using both DIOL functionalized particles and PGC as packing material. In the DIOL system, one analogue of ZGP with an esterified acid function (L-ZGP methyl ester) and one lacking the glycyl group (Z-L-proline) have been tested. It was found that the acidic function is needed and that this function, together with the keto group in the benzyloxycarbonyl group, was enough for enantioselectivity. Exchanging the glycyl in L-ZGP for L-alanyl will, however, completely ruin the stereoselectivity and the methyl group in alanyl is believed to block the hydrogen-accepting

Figure 6 Resolution of D,L-dansyl-valine. Solid phase: LiChrosorb DIOL. Mobile phase: Quinine and acetic acid 0.35 mM in dichloromethane (dry) + 1-pentanol (99 + 1). keto group. Reversing the positions of alanine and proline restores the selectivity to some extent (Table 4).

The aromatic function in L-ZGP provided by the *N*-blocking benzyloxycarbonyl group seems not to be a prerequisite for chiral recognition as a low enantioselectivity has been observed for some solutes using *N*-cyclopentylpropionyl-L-proline as chiral selector. Thus, when using a DIOL stationary phase, chiral recognition is believed to involve an electrostatic attraction to the acidic function in L-proline and hydrogen bonding to the carbonyl group.

Several selectors structurally related to L-ZGP have been studied in systems with PGC as support. In Table 6, the results from one of these studies is presented. L-ZGP, *N*-benzyloxycarbonyl-glycylglycyl-L-proline (L-ZGGP) and 1-[(2*S*)-3-mercapto-2-methylpropionyl]-L-proline (captopril) may be re-

garded as three supplementary selectors. Although all three show enantioselectivity for metoprolol, L-ZGP is not 'usable' for metoprolol analogues having a distance larger than two carbons between the hydroxyl and amine function. In order to match the increase in the distance between possible points of interaction, introduction of a hydrogen-bonding group further apart in the selector promotes the enantioselectivity.

Recently, two new *N*-derivatized dipeptides, *N*-benzyloxycarbonyl-L-glutamyl-L-proline (Z-L-Glu-L-Pro) and *N*-benzyloxycarbonyl-L-glutamyl-D-proline (Z-L-Glu-D-Pro), have been reported. Only one of the dipeptides, Z-L-Glu-L-Pro, shows enantioselectivity for the amino alcohols studied (metoprolol and analogues), although ion pairing occurred with both peptides. The possibility of using Z-L-Glu-L-Pro at temperatures above ambient has been investigated. In contrast to using L-ZGP, the enantioselectivity is, however, only slightly affected when increasing the temperature. Although the retention is decreasing at elevated temperatures, the enantiomers of, for example, metoprolol, may be separated within a wide temperature range, 10 to 45°C. An enantiomeric separation of metoprolol is given in Figure 7. It may also be worth noting that the elution order of the enantiomers were opposite using Z-L-Glu-L-Pro and L-ZGP as selectors, even though in both cases the terminal peptide was L-proline. The relative retention order of the studied amino alcohols was independent of the selector used, L-ZGP or Z-L-Glu-L-Pro.

xyephedrine are separated within 4 min.

General Mobile Phase Considerations

Beside the counterion and its concentration, the composition of the mobile phase will depend on the column packing material used and the type of solutes to analyse. Uncharged or charged modifiers may be needed in the mobile phase in order to elute the solutes in a reasonable time and also to resolve them into their enantiomers.

Mobile Phase Composition when using DIOL Functionalized Silica as Stationary Phase

When DIOL functionalized silica particles are used as stationary phase, the mobile phase has to be a non-polar solvent. The water concentration in the non-polar solvent may then be of vital importance for the success of the separation and should, together with some of the chiral counterions, quinine and camphor-

sulfonic acid, be as low as possible in order to promote the chiral separations. The equilibration time needed to obtain a stable system with dry solvent is, however, very long and therefore it is convenient to work with higher water contents although not a water-saturated mobile phase. The water content does not influence the enantioselectivity when L-ZGP is used as counterion. Longer retention times are, however, obtained when more water is present in the solvent. Water-saturated injection solutions can be injected into the system without influence on either retention or stereoselectivity.

As the polarity of the mobile phase controls the retention of the solutes, modifiers like alcohols, acetonitrile or tetrahydrofuran have sometimes to be used in order to elute solutes in a reasonable time. Several of these modifiers also have an effect on the enantioselectivities of these systems. Some modifiers have been studied in a system with (+)-10-camphor-sulfonate in dichloromethane as mobile phase. (In these cases the mobile phases were prepared from dry dichloromethane.) It was found that the stereoselectivity was lower with hydrogen donating modifiers than with hydrogen accepting ones (Table 7). One hypothesis is that the modifiers may interact with the hydrogen-bonding groups in the selectors. It should be noted that 1-pentanol is preferred as a modifier since the peaks obtained are more symmetrical than

when using, for example, tetrahydrofuran. The improved peak shape is believed to be due to deactivation of strong adsorption sites on the silica surface.

Peak shapes may also be improved by adding to the mobile phase a compound with the same protolytic character as the solute enantiomers. Thus, for the separation of amines, triethylamine is often used to improve peak symmetry. Acidic compounds to be analysed with, for example, quinine, may need addition of acid to the mobile phase in order to effect elution. The added acid is believed to compete for adsorption to the solid phase and for ion pair formation with quinine.

Mobile Phase Composition when using PGC as Stationary Phase

When PGC is used as stationary phase, both nonpolar and polar mobile phases may be used. The nonpolar

Figure 7 Separation of (R)- and (S)-metoprolol. Solid phase: Hypercarb. Mobile phase: 3.4 mM Z-L-Glu-L-Pro and 5.5 mM NaOH in methanol. Column temperature: 35°C. phases resemble those used with the DIOL stationary phase. The addition of a nonchiral hydrophobic acid may, however, be needed in order to elute some of the hydrophobic acids from the PGC. Naproxen was found to be too strongly retained using a mobile phase consisting of quinine in dichloromethane and hexane. When adding β -naphthalenecarboxylic acid to the mobile phase, naproxen was eluted within a reasonable time and the enantiomers were separated (Figure 9). The effect of addition of an acid to the mobile phase is not easy to predict as the added acid may compete for both the distribution to limited adsorption sites on the support and also for ion pair formation with the chiral selector. Furthermore, if the counterion added to the polar mobile phase is expected to remain in an uncharged form, an acid or base has to be added in order to obtain a charged counterion. L-ZGP has a pK_a of 7–9 in methanol. The amount of base added (e.g., sodium hydroxide) will determine the degree of protolysis of the L-ZGP. However, an excess of base will result in an alkaline solution where the solutes may be uncharged. The added base may thereby influence the retention and the stereoselectivity, in other words influence both k and the ratio $k_{\text{achiral}}/k_{\text{chiral}}$ (Figure 3).

Conclusions

The addition of a counterion to the mobile phase is a technique often used to control the retention of solutes. If the added counterion is chiral, chiral separations may be achieved provided that appropriate

solvents and solid supports are chosen. Using mobile phase additives is an easy way to screen for new chiral selectors. Furthermore, if the chiral counterion is

available in both its enantiomeric forms, the retention order of a pair of enantiomers may be controlled. In contrast to derivatization with chiral reagents, there is no need for optically pure counterions or counterions with exactly known purities. An optically impure selector will, in chiral ion pair chromatography, still give enantiomerically pure peaks, although eluting closer to each other than they would if an optically pure selector were used.

Ligand Exchange Chromatography

V. A. Davankov, Nesmeyanov-Institute of Organo-Element Compounds, Russian Academy of Sciences, Moscow, Russia

Copyright © 2000 Academic Press

Introduction

Ligand exchange chromatography (LEC) was first introduced by Helfferich in 1961 as a general chromatographic technique to separate compounds which are able to form labile complexes with transition metal cations. The basic idea was to immobilize such ions as Cu(II) or Ni(II) on a stationary phase, in particular, a cation exchanger with sulfonic or carboxylic functional groups, and then let the ions form labile coordination compounds with analytes which possess electron-donating functional groups and can enter the coordination sphere of the metal ion, thus acting as ligands. Those analytes that form stronger complexes with the central ion, are retained longer on such a metal ion-incorporating stationary phase.

Starting with the idea that, in the densely packed coordination sphere, ligands enter multipoint interactions with each other and should therefore mutually recognize the spatial configuration of neighbours, Davankov and Rogozhin (1968–71) synthesized chiral complex-forming resins and further developed LEC into a powerful chiral chromatographic method. This technique, for the first time in liquid chromatography, resulted in a complete and reliable resolution of a racemate into constituent enantiomers. Typical analytes for enantioselective LEC are members of such important classes of chiral compounds as amino acids, hydroxy acids and amino alcohols. Having soon become one of the most extensively investigated methods for the direct resolution of enantiomers, LEC maintained for a long period of

time its leading positions in developing novel chiral chromatographic systems and evaluating mechanisms of chiral recognition and discrimination. This technique contributed much to the successful development of chiral silica-bonded stationary phases, both monomeric and polymeric, chiral coatings on column-packing materials and chiral mobile phase additives. In this last technique, it transpired that the central metal ion does not need to reside in the stationary phase, but, instead, can be a part of a chiral complex that is doped into the mobile phase to interact there with the analytes. This widens significantly the definition of LEC to a chromatographic process in which the formation and breaking of labile coordinate bonds to a central metal cation are responsible for the separation of complex forming analytes.

Ligand exchange has been realized in all known modes of enantioselective chromatography, including liquid chromatography, thin layer chromatography, gas chromatography, capillary electrophoresis and countercurrent liquid chromatography. In gas chromatography the principle of ligand exchange is more commonly known under the name ‘complexation chromatography’.

Theoretical Aspects of Chiral Discrimination in LEC

Being built of protons, neutrons and electrons, which basically are chiral elementary species, all atoms possess inherent chirality. Therefore, two enantiomeric molecules resulting from a mirror-symmetric arrangement of a certain ensemble of atoms in space, can differ in their thermodynamic stability. However, this difference may only amount to about 10^{-14} J mol⁻¹, which practically makes the enantiomers energetically identical and indistinguishable in any achiral environment. Using any chromatographic technique, two enantiomers can be recognized and

discriminated by the action of a chiral selector only. The latter has to be involved in interaction with the enantiomers, resulting in the formation of adducts which, being diastereomeric species, may differ in their stability. These adducts in LEC are ternary complexes composed of the molecule of the chiral selector, the complexing metal ion, and the enantiomer to be recognized. Thermodynamic enantioselectivity of the system, i.e. the difference in stability of the above two diastereomeric ternary complexes which incorporate (*R*) or (*S*) enantiomers of the analyte, represents the sole source of chiral discrimination of the enantiomers in LEC. For an analytical scale resolution of enantiomers, the enantioselectivity does not need to be high, since, in principle, enantioselectivity of $\delta\Delta G^0 = 25 \text{ J mol}^{-1}$ would correspond to a separation factor $\alpha = 1.01$, which is fully sufficient for two peaks to be resolved in a gas chromatographic capillary column generating about 10^5 theoretical plates. For a preparative scale liquid chromatography, one would prefer to deal with a separation factor of at least $\alpha = 1.5$, which would correspond to enantioselectivity of about 1 kJ mol^{-1} . Ligand exchange often generates a discrimination effect of this order of magnitude. With the $\delta\Delta G^0$ increasing further, the column selectivity, α , rises exponentially, according to the general relation $\delta\Delta G^0 = RT \ln \alpha$. In LEC systems with polydentate ligands, separation selectivities of up to $\alpha = 10$ are known.

As a matter of principle, a chiral selector has to enter into at least a three-point interaction with the enantiomers, in order to be able to recognize the difference in the spatial structure of the latter. This requirement is easily met with tridentate ligands forming ternary complexes with metal ions which have a coordination number of six. Among practically important classes of organic compounds, however, are molecules with two electron-donating heteroatoms, N and/or O, situated in a chain of carbon atoms in positions 1,2 or 1,3, e.g. in 1,2- and 1,3-diamines, 1,2- and 1,3-amino alcohols, α - and β -amino acids and α - and β -hydroxy acids. When forming complexes with metal ions, these compounds usually function as bidentate ligands with both heteroatoms coordinated to the same metal ion in the form of a five- or six-membered chelate ring.

It is very important that formation and dissociation of the bonds in the coordination sphere of the metal ion be fast. Otherwise, a slow rate of ligand exchange would degrade the efficiency of the chromatographic system. Therefore, only metals forming kinetically labile complexes can be employed in LEC, preferably Cu(II), Ni(II) and Zn(II). Even with the above metal ions, it has been repeatedly reported that the efficiency of ligand exchanging systems can be enhanced by

raising the column temperature to about 50°C , which speeds up the ligand exchange. Ions of Cr(III), Co(III), Pd(II) and the like, form kinetically inert, stable complexes unsuitable for LEC. However, the second coordination sphere of these complexes, which actually is their solvation shell, is well organized, too, and it does exchange its ligands readily, so that an enantioselective chromatography process can also be based on outer coordination sphere ligand exchange.

Zn(II) would usually coordinate four heteroatoms with lone electron pairs in the form of a tetrahedron. The coordination number of the Ni(II) ion is six and its ligands are usually arranged in an octahedron. Copper binds four ligands in its main coordination square, but offers two additional, more remote axial positions, so that a complex with the coordination number six adopts a distorted octahedral structure.

It is worth noting, that the optical purity of a complex-forming chiral selector employed in an LEC system does not need to be necessarily 100%. It is a distinguishing feature of all direct chromatographic separations of enantiomers that even a selector contaminated by its enantiomeric form can provide a complete resolution of racemic analytes. Enantiomeric impurities in the chiral selector do not diminish column efficiency but merely result in the two sharp enantiomeric peaks of the analyte approaching each other and completely coalescing into one sharp peak when the enantiomeric excess (e.e.) of the selector falls to zero. This phenomenon (which is not an issue, at all, with proteins or natural carbohydrates as the chiral selectors, since these selectors are available in only one enantiomeric form) has been repeatedly proven experimentally in chiral exchanging systems involving amino acids of known e.e. as the selector.

Chiral-Bonded Ligand Exchanging Stationary Phases

The first chiral ligand exchanging polystyrene-type stationary phases were synthesized and tested by Rogozhin and Davankov as early as 1968, while analogous silica-bonded phases emerged a decade later. Even nowadays, cross-linked polystyrene resins remain popular in preparative chromatography, mainly due to their excellent chemical durability and high loading capacity. To prepare such chiral packings, spherical particles of styrene-divinylbenzene copolymers are usually subjected to chloromethylation and the active chlorine atoms are then replaced by amino groups of chiral natural α -L-amino acids, in particular (*S*)-proline and (*S*)-hydroxyproline.

(According to modern stereochemical nomenclature, L- and D- α -amino acids belong to R and S configuration series, respectively, with a few exceptions, however.) The structure of a chiral selector immobilized in this way as well as its complex with a Cu(II) ion and an amino acid analyte, both of which bind to the selector during the process of LEC, can be represented by the following scheme:

tate amino acid-type ligands, like histidine or alloxypyrroline, the opposite elution order of the enantiomers is observed, thus giving α values smaller than 1. Many other types of chiral selectors have been similarly immobilized on chloromethylated cross-linked polystyrene beads, with the result that cyclic amino acids as well as benzyl-substituted chiral propan-1,2-diamine display the highest selectivity and largest application range. Typical examples for resolving racemates of common α -amino acids on these phases are presented in Table 1.

Two additional polymeric matrixes, cross linked polyacrylamide and poly(glycidylmethacrylate), have also been shown to be useful for immobilizing chiral amino acid selectors. The mode of functionalizing of these resins, when they incorporate (S)-phenylalanine and (S)-proline as typical chiral selectors, can be represented by the following structures:

Here, the most important features of the ternary mixed-ligand bis(amino acidato)copper complex are:

- the formation of two five-membered chelate rings;
- the occupation of the four positions of the Cu(II) ion main coordination square by four electron-donating atoms of the ligands;
- the *trans*-arrangement of the two negatively charged carboxyl groups and the bi-substituted nitrogen atoms, respectively, which minimizes both the electrostatic and sterical repulsion of the ligands in the complex.

The resins incorporating (S)-proline and (S)-hydroxyproline, when loaded with Cu(II) ions and eluted with ammonia solution, are usually found to retain α -amino acids of the opposite, (R)-configuration more effectively. In this case, the enantioselectivity of the system, when expressed as the ratio of retention factors of the (R)- and (S)-enantiomers of the analyte, $\alpha = k_R/k_S$, is larger than 1. With triden-

The first resin demonstrates higher affinity to (R)-isomers of all amino acids, without any exception, resolving all racemates with a selectivity of at least $\alpha = 1.3$.

All the above polymeric ligand exchangers have been used successfully for both analytical and preparative resolution, e.g. for obtaining highly radioactive tritium-labelled optically active amino acids. In order to remove trace copper ions from enantiomers resolved in preparative experiments, the fractions of interest can be gravity filtered through a small additional column packed with silica, any chelating resin or even the same chiral resin, with a blue band of Cu(II) gradually forming at the top of the subsidiary column.

Silica-bonded chiral ligand exchangers were expected to demonstrate in analytical-scale separations still better column efficiency than polymer gels. Three types of bonded phases were suggested independently and simultaneously in 1979 by the groups of Foucault, Davankov and Guebitz, based on three different ways of activating the initial macroporous

Table 1 Enantioselectivity, $\alpha = k_D/k_L$, of resolution of racemic amino acids on the Cu(II) forms of polystyrene resins which incorporate residues of L-proline, L-hydroxyproline, L-allo-hydroxyproline, L-azetidine carboxylic acid and *N*-benzyl-(*R*)-propane-1,2-diamine. microparticulate silica gel, namely, by first grafting silica with aminopropyl, chloroalkyl, and 3-glycidoxypentyl groups, respectively:

Whereas the aminopropyl spacer binds a chiral amino acid-type selector via the carboxyl group, the other two functions easily react with the amino group of the selector. The epoxy-activated and L-proline incorporating silica was the first chiral-bonded stationary phase on the market (Chiral ProCu, Serva, Heidelberg, Germany). Silica-bonded ligand exchangers have been used successfully to resolve racemates of numerous amino acids, hydroxy acids, *N*-dansyl- and *N*-alkyl-amino acids, α -trifluoromethyl- α -amino

acids, dipeptides, some β -amino acids, etc. Amino alcohols do not form stable chelates with Cu(II) ions, but are easily resolved after conversion into Schiff bases or, better still, after reaction with bromoacetic acid, which converts the amino group into a chelating glycine moiety.

The silica-bonded phases, however, still require elevated temperatures (usually 50°C) to generate sufficient column plate numbers. In addition only neutral or weakly acidic aqueous-organic eluents, in particular, in the pH range between 6.0 and 4.0 can be applied. Therefore, a much more hydrolytically stable packing was introduced by multiple-point binding of chloromethylated polystyrene chains to the silica matrix, followed by substituting the active chlorine atoms of the polymer for chiral selectors. This type of polymer-bonded phase can safely be used at elevated temperatures, and display high resolving power towards numerous racemates, as exemplified in Figure 1. In LEC, the elevated temperature does not noticeably affect the enantioselectivity of the column.

Figure 1 Enantiomeric resolution of a mixture of eight DL-amino acids with a chiral stationary phase, polystyrene grafted on silica gel and substituted with L-Hydro. Conditions: column, 250 × 4 mm i.d., dp 5 µm; eluent, 0.5 mM copper acetate, 10 mM ammonium acetate, pH 4.5, acetonitrile 30%; flow rate, 0.7 mL min⁻¹; temperature, 75°C; UV 254 nm. (Reprinted with permission from Davankov VA (1989) Chapter 15, Figure 5, p. 464. In: Krstulovic AM (ed.) *Chiral Separations by HPLC. Applications to Pharmaceutical Compounds*, pp. 446–475. Chichester, England: Ellis Horwood.)

When dealing with complicated analyte matrixes, it is often useful to combine in sequence a chiral column with a conventional achiral one, in order to supplement the resolution of enantiomeric pairs in the chiral column with the selectivity towards different analytes of the second column. Thus, chiral ligand exchanging bonded phases are easily compatible with achiral reversed phase columns, since both columns can be operated in a gradient mode with aqueous-organic eluents which contain about 0.1 mM copper acetate and about 0.25 M ammonium acetate.

Several silica-bonded and polymeric chiral ligand exchangers are commercially available, e.g. Chiral-Si 100 L-ProCu, Chiral-Si 100 L-ValCu, Chiral-Si 100 L-HyProCu (Serva, Heidelberg, Germany), Nucleosil Chiral-1 (Macherey-Nagel, Dueren, Germany),

Chiralpak WH and WM (Daicel, Japan), TSK gel Enantio L1 (Toso, Japan), MCI gel CRS 10W (Japan), Chirosolve L-proline, Chirosolve L-valine (JPS Chimie, Switzerland). Any scientific evaluation of results obtained by using these phases is, however, complicated, since the exact structure of immobilized chiral ligands on many commercially available chiral stationary phases is not specified by the manufacturers.

Chiral Dynamically Coated Stationary Phases

Ligand exchanging columns of an exceptional efficiency and enantioselectivity can be easily prepared from commercially available reversed-phase columns by dynamically coating the column with a hydrophobic chiral selector. According to the technique suggested by Davankov and Unger in 1980, percolating a solution of *N*-alkyl-L-hydroxyproline in aqueous methanol through the column results in depositing the chiral selector on the bonded alkyl stationary phase. After a subsequent saturation of the retained ligand with copper ions, the column is ready for racemate resolutions in water-rich eluents which do not desorb the chiral selector. Depending on the length of the *N*-alkyl group (heptyl, decyl or hexadecyl) and conditions of coating, the amount of the chiral selector deposited can be easily regulated over a very broad range. Such columns (also commercially available from Regis Technologies, USA, as 'Davankov columns') display a high resolving power toward numerous amino acids (Figure 2) and their derivatives, racemic glycyl-di- and tripeptides, 3-amino-ε-caprolactam, as well as norephedrine and its analogous amino alcohols. Interestingly, the *N*-alkyl-L-hydroxyproline-coated columns, under severe overloading conditions, show a peculiar distortion of elution profiles of the enantiomers in that the first peak has no tail whereas the second peak shows a very sharp front, which enormously increased the column loadability, implying high preparative potential of the system.

Coating reversed-phase columns with *N,N*-dioctyl-L-alanine has proved especially efficient in resolving racemic α-hydroxy acids. Chiral coatings prepared with *N*²-decyl-L-histidine, *N*¹⁰-decyl-L-histidine, *N*²-octyl-(L)-phenylalaninamide, *N,S*-dioctyl-*N*-methyl-(D)-penicillamine, hydrophobic Schiff bases of chiral amino alcohols and *N*-dodecyl-*N*-carboxymethyl-(1*S*,2*R*)-norephedrine show high efficiency and selectivity. Reversed-phases coated with *N,S*-dioctyl-(D)-penicillamine and (*R,R*)-tartaric acid mono-(*R*)-1-(α-naphthyl)ethylamide are commercially available under the name Sumichiral OA-5000 and 6000 (Sumica Chemical Analysis Service, Japan).

Figure 2 Enantiomeric resolution of a mixture of seven DL-amino acids with a chiral coating of *N*-decyl-L-Hypro on reverse phase material. Conditions: column, 100 × 4.2 mm, LiChrosorb RP 18, dp 5 μm; eluent, methanol-water (15 : 85), 0.1 mM Cu(II) acetate, pH 5.0; flow rate 2 mL min⁻¹; temperature 20°C, UV 254 nm; elution sequence; 1, L-Ala; 2, D-Ala; 3, L-Val; 4, L-Arg; 5, D-Arg; 6, L-Leu; 7, L-Nleu; 8, D-Val; 9, L-Phe; 10, D-Leu; 11, L-Trp; 12, D-Nleu; 13, D-Phe; 14, D-Trp. (From Davankov VA, Bochkov AS, Kurganov AA, Roumeliotis P and Unger KK (1980) Separation of unmodified α-amino acid enantiomers by reverse phase HPLC. *Chromatographia* 13: 677–685, Figure 2, p. 680.)

Whereas long *N*-alkyl substituents of the above chiral selectors are best suitable to bring about the intercalation of the latter between the surface alkyl groups of the reversed phase support, porous graphite offers a flat and rigid surface for the chiral selector to stick to. In this case, polyaromatic substituents show better retention and resolving power of the coated chiral selector, as is the case with *N*-naphthylmethyl-L-proline or *N*-(2-naphthalenesulfonyl)phenylalanine (see Figure 3).

Similarly, hydroxylated macroporous silica gel can be coated with hydrophilic chiral selectors such as silver(I)-*d*-camphor-10-sulfonate or (+)-cobalt(III)-tris-ethylenediamine trichloride. In non-aqueous media, these phases easily resolve racemates of some chiral diene and cyclopentadienylrhodium(I)-norbornadiene complexes. Since in the latter case ethylenediamine ligands of the inert cobalt complex are not exchanged for any new ligands, the separation

should be ascribed to ligand exchange in the outer, solvation shell of this complex.

Finally, polymeric chains of polyacrylamide grafted with L-proline can also be permanently adsorbed onto the surface of silica gel, to give a chiral ligand exchanger which resolves amino acids in polar media.

The ease of preparation of chiral-coated ligand exchanging phases, their exceptional efficiency, durability, wide application range and the opportunity of regulating the elution order of the enantiomers of interest by simply changing the configuration of the selector applied, make the technique increasingly popular.

Chiral Ligand Exchanging Mobile Phases

In the technique described in the previous section, the chiral selector permanently resides on the surface of

Figure 3 Enantiomeric separation of racemic amino acids and hydroxy acids with a chiral coating of *N*-(2-naphthalenesulfonyl)-L-phenylalanine on porous graphite. Conditions: column PGC 94F (5 μ m, 50 \times 4.6 mm), eluent 2.0 mM Cu(CH₃COO)₂, pH 5.6, flow rate 0.5 mL min⁻¹, UV 254 nm, temperature 30°C. (Reprinted with permission from Knox JH and Wan Q-H (1995) *Chromatographia* 40: 9–14.)

the column packing. The coating is deposited prior to the chromatographic experiments and no eluents should be used which cause a leakage of the selector. A different approach, which was independently suggested in 1979 by the groups of Karger and Lindner and Hare and Gil-Av, consists in using chiral selectors which predominantly reside in the mobile phase. In this case, the selector complex has to be continuously introduced into the column. Analytes to be resolved in such a chiral eluant form mixed-ligand complexes with the selector, which are diastereomeric in their structure, and, therefore, may be differently retained through the interaction with the column packing. A great advantage of this technique is that many different chiral selectors can be easily tested with respect to the analyte to be resolved. Another advantage is that smaller ligands are usually applied as the eluent dopants, which results in enhanced rates of ligand exchange and better efficiency of the columns. A disadvantage is the loss of the chiral selector and problems of separating the selector from the enantiomers resolved in the case of preparative experiments. It should be emphasized also that the two enantiomers separated in the achiral column enter the de-

tector cell with the chiral eluent in the form of ternary complexes. These complexes are diastereomeric and can significantly differ in molar extinction. Indeed, a case of enantioselective fluorescence quenching of dansylamino acids by a chiral Cu(II) complex of L-phenylalanylamide in aqueous solutions has been reported, thus requiring two calibration curves for a quantitative determination of the two enantiomers.

In combination with Cu(II), Zn(II), Ni(II) and some other transition metal ions, many chiral selectors have been shown to function successfully in reversed phase systems as chiral dopants. They mainly belong to the following classes of chelating compounds:

- unsubstituted L- α -amino acids (proline, phenylalanine, isoleucine, histidine, etc.);
- N-alkyl-L-amino acids (N-benzyl-proline, N,N-di-propyl-alanine, N,N-dimethyl-valine);
- L- α -amino acid amides (valine amide, phenylalanine amide, prolyloctylamide, aspartyl-alkylamide);
- esters of L- α -amino acids (histidine methyl ester);
- peptides (prolyl-valine, aspartylphenylalanine methyl ester or aspartame);

- chiral diamine (*N,N,N',N'*-tetramethyl-(*R*)-propanediamine-1,2-(*L*)-alkyl-4-octyl-diethylene-triamine);
- mandelic acid;
- derivatives of (*R,R*)-tartaric acid (tartaric acid mono-*n*-octylamide);
- nucleotides (adenosine diphosphate, β -nicotinamide, adenine dinucleotide and, in particular, flavine adenine dinucleotide).

Mainly racemic α -amino acids and their numerous derivatives, α -hydroxy acids and amino alcohols are successfully resolved. Less common, but nevertheless successful, are resolution of substituted pterins, phenylhydantoins and ornithine analogues.

Depending on the hydrophobicity of the analyte and chiral selector applied, the content of the organic modifier in the chiral mobile phase has to be adjusted in such a manner that the retention of enantiomers remains in the desired time window. In addition to this parameter, retention (and enantioselectivity) in LEC would slightly decrease with the rise in the ionic strength of the eluent and temperature of the column. Conversely, rising pH and concentration of the chiral additive in the mobile phase cause a clear increase in retention and a less marked increase in enantiomeric resolution.

Under normal phase conditions, with bare silica gel as the packing, copper complexes of *N,N,N',N'*-tetramethyl-(*R*)-propane-1,2-diamine can be used to resolve amino acids and mandelic acid. Bis(*L*-prolinato)copper is efficient even in combination with sulfonated polystyrene cation exchangers, which additionally demonstrates the versatility of the chiral mobile phase approach.

The high efficiency of the method is exemplified by Figure 4.

It is easy to imagine that, by using a mobile phase with a chiral selector of the opposite configuration, we reverse the elution order of the resolved enantio-

mers. This approach is useful in analysing enantiomeric impurities in chiral compounds, where it is always advisable to have the trace component eluting before the major enantiomer.

Finally, it is worth mentioning that the chiral mobile phase mode of LEC is very convenient to prove the reciprocity relations in chiral recognition, where the selector is exchanged for the analyte and vice versa. The enantioselectivity of the system should remain the same, unless some additional factors interfere with the essential interactions within the diastereomeric sorption complexes.

Mechanisms of Chiral Discrimination in LEC

Of many enantioselective chromatographic systems developed thus far, ligand exchanging systems are the most examined. Understanding of the mechanism of chiral discrimination is greatly facilitated here by the fact that, of the three interactions needed for the chiral selector to recognize the solute enantiomers, two are well defined as the *trans*-coordination bonds of pairs of carboxylic and amino groups in the main coordination square of the Cu(II) ion. The third interaction should be looked for in the out-of-plane sterical interactions or coordination in remote axial positions of the coordination sphere. Thus with *L*-proline or *L*-hydroxyproline incorporating polystyrene-type resins, retention of *L*-isomers of amino acids is diminished by sterical interactions with the water molecule coordinated in one of the axial positions. On the other hand, the binding of *D*-isomers is facilitated by favourable hydrophobic interaction between the solute α -substituent and the polystyrene matrix, as shown below:

Tridentate amino acids, *L*-His, *L*-Asp, *L*-Glu, *L*-aHyp, manage to replace the water molecule from the axial position and form one additional coordination

Figure 4 Enantiomeric separation of *R,S*-hydroxy acids with a chiral mobile phase. Conditions: 8 mM L-PheNH₂, 4 mM Cu(CH₃COO)₂, pH 6.0, ambient temperature, column Spherisorb 3 ODS-2 (3 μ m, 150 \times 4.6 mm), flow rate 1 mL min⁻¹, postcolumn derivatization with Fe(ClO₄)₃, UV 436 nm. Other Chromatographic and Related Techniques of Resolving Enantiomers in Ligand Exchanging Systems

In gas chromatography, ligand exchange has acquired great importance since Schurig introduced metal complexes of chiral terpeneketonate (acylated camphor, carvone, pulegone, menthone) as additives to stationary phase in capillary GC in 1977. Ni(II), Mn(II), Cu(II), Zn(II), and Rh(I) proved especially useful in this 'complexation' chromatography. The resolution mechanism is ascribed in terms of the interaction between the above sterically or electronically unsaturated metal chelates with volatile ligands which offer lone electron pairs to form a labile mixed-ligand sorption complex. Enantioselectivity of this process is small, but, due to the extremely high plate numbers attainable with capillary GC columns, excellent resolution is achieved for many classes of alkenes, alcohols, ethers, oxirane, sulfur-containing compounds, aziridine, etc. It is important that even compounds containing one single electron-donating atom (O, N, S) are successfully resolved by GC, contrary to LC, where the presence of two donors to form a chelate with the central metal ion is highly desirable.

Similar bonded chiral selectors, e.g. polysiloxane-anchored Ni(II)-bis-[(3-heptafluorobutanoyl)-(1*R*)-camphorate], Chirasil-Nickel, can also be used in the supercritical fluid chromatography (SFC) mode. Although SFC cannot compete with GC with regard to efficiency, a significant increase in selectivity, due to a substantially lower temperature of the column, can compensate for the loss in plate number. Because of the high solvation strength of supercritical carbon dioxide, a number of low-volatility racemic alcohols, diols and esters have been resolved by ligand exchange SFC at temperatures as low as 40–70°C.

In capillary electrophoresis (CE) and other electromigration techniques, chiral ligand exchange can be involved in several ways. Cu(L-His)₂ has just been added to the ammonium acetate electrolyte to induce chiral resolution of dansylated amino acids. Analyte enantiomers which are strongly involved in the formation of positively charged mixed complexes with Cu(L-His) move toward the cathode at a higher rate than the uncomplexed ligands. Since the enantioselectivity of the ligand exchange reaction in the bulk solution is small, the resolution of enantiomers is also small. It is only slightly better with copper-aspartame as chiral additive. A significant improvement in selectivity can be obtained by adding tetradecyl sulfate, as a micelle-forming surfactant. Obviously, the enantioselectivity increases through the interaction of the diastereomeric ternary complexes

Figure 5 Electrophoregram of the enantiomer separation of DL-Phe, DL-Trp and DL-MeTrp with and without SDS. Conditions: (a) 80 mM L-Hyp, 40 mM Cu(II) sulfate, pH 4.0; (b) 50 mM L-Hyp, 25 mM Cu(II) sulfate, 15 mM SDS, 3 M urea, pH 4.0. Capillary: fused silica, 75 cm \times 75 μ m i.d. (effective length, 66 cm) $U = 27$ kV, UV 208 nm, ambient temperature. (Reproduced with permission from Schmid MG and Guebitz G (1996) *Enantiomer* 1: 23–27. Gordon and Breach Publishers.)

with the surface of the pseudo-stationary micelle phase. Good resolution for dansyl (DNS) amino acids has been obtained with mixed-micelle solutions containing sodium dodecyl sulfate (SDS) and copper complexes of *N,N*-didecyl-L-alanine. Figure 5 shows an example of CE resolution of underivatized racemic amino acids with Cu(L-Hyp)₂ in the support electrolyte, which is facilitated by SDS micelles. Note the inversion of the elution order of the enantiomers and solutes on transition from the homogeneous support electrolyte solution to the pseudo-heterogeneous micellar system.

In addition to paper chromatography which represents the oldest chiral planar chromatography tech-

nique, ligand exchange opened enormous possibilities for chiral thin-layer chromatography. Macherey-Nagel in cooperation with Degussa (Germany) developed reversed-phase plates coated with copper complexes of *N*-(2-hydroxydodecyl)-L-hydroxyproline in the manner described earlier by Davankov for chiral coating of RP-columns. The Chiralplate® has proved to be extremely versatile in the resolution of racemic α -amino acids, their *N*-methyl-, *N*-formyl-, α -alkyl-, and halogenated amino acids, dipeptides, α -hydroxy acids, thiazolidine derivatives, anomers of several nucleobases, etc. Copper complexes of *N,N*-dialkyl amino acids have also been tested as chiral coatings of plates, but so far have not found broad application.

Finally, enantiomeric separation of phenylalanine and lactic acid by diffusion through a liquid membrane was studied, using a solution of *N*-decyl-L-hydroxyproline copper complexes in hexanol-decane mixtures as the membrane. The rate of migration of the D-Phe was found to be about 2.4 times faster as compared to those of the L-isomer. Though the productivity potential of the technique is high, the above value of the kinetic enantioselectivity is still insufficient for practical use.

Applications

Two principal advantages of chiral LEC should be mentioned with respect to practical application of the method. Firstly, the detection of compounds which do not absorb in the near UV region is greatly facilitated by the fact that they partially elute from the LEC column in the form of metal complexes. Even having no strong chromophore in the molecule, they strongly absorb at 254 nm in the complexed form. When complexed to Fe(III), hydroxy acids can be selectively detected at 420 nm. The second great advantage of ligand exchange is that enantioselectivity of the separation is largely unaffected by the temperature of the column and the presence of buffer salts and organic modifier in the eluent. This makes the method easily compatible with numerous other separation techniques, including multidimensional and multicolumn chromatography.

In general, the efficiency and easiness of the direct resolution of amino acids and hydroxy acids, without any prior derivatization of the analyte, make LEC a technique of choice for serial determinations of enantiomeric compositions. This is the case, for example in fossil dating where, depending on the rate of racemization of the amino acid under investigation, the dating can be performed in the time range from several hundred years to one million years. Another application area of this kind is the

determination of D-amino acids in food products caused by partial racemization through heat or microwave treatment, and to fermentation processes. Occurrence of D-amino acids in biological fluids (e.g. serum, cerebrospinal fluid, urine), bone and tissues is also of great importance from a diagnostic point of view. Rapid enantiomeric analysis techniques are needed when asymmetric synthesis or chemical or enzymic racemate resolution processes are being developed. Examination of the enantiomeric composition of hydroxy acids, in particular malic acid, helps to investigate adulteration of apple juice and other soft drinks. Rapid preparation of enantiomers of compounds labeled with highly radioactive atoms, where only dilute solutions can be handled, is another excellent application area for chiral LEC.

Three decades of the existence and intensive development of enantioselective LEC have shown this technique to be an extremely versatile and productive general approach to resolving racemates of compounds that form complexes with metal ions. Other types of molecular interactions have been later found to provide alternative successful ways of organizing the formation of labile diastereomeric adducts with appropriate chiral selectors, e.g. formation of inclusion complexes of analytes with cyclodextrins and cyclic antibiotics or formation of charge-transfer complexes between electron-donating and electron-deficient aromatic groups in Pirkle-type chiral stationary phases. Designing novel chiral selectors which simultaneously offer to the analyte several different modes of interactions could probably result in developing chiral chromatographic systems with wider application areas or higher enantioselectivity with respect to particular important racemates. Thus first attempts of providing cyclodextrins with a copper complexed residue moiety have recently been reported in the literature. Another practically unexplored field for further development could be ligand exchange in nonaqueous and even nonpolar media. With the solvent molecules not competing for the coordination positions of the metal ion, much weaker electron donors than carboxylic or amino functional group of the analyte, should suffice for the complex formation. Ether, sulfide and carbon-carbon double bonds should thus be suitable for complexation. Achievements of complexing gas chromatography and 'argentation' thin-layer chromatography corroborate the feasibility of this development of

ligand exchanging enantioselective column liquid chromatography.

A pair of enantiomers only differ in their optical rotation, but their physical properties such as melting point, boiling point, refractive index and solubility are identical. On the other hand, the physical and chemical properties of a pair of diastereomers are different. For the separation of enantiomers by liquid chromatography, it is essential to form a diastereomeric complex in the mobile phase or in the stationary phase or to convert to diastereomers. The former is called the direct method, and is based on the addition of chiral additives to the eluent or the use of chiral stationary phases, resulting in the formation of a diastereomeric complex in the mobile or stationary phase. The second indirect method is based on the reaction of the enantiomers with a homochiral reagent, resulting in the formation of a pair of diastereomers. This article deals with both the indirect and direct methods using liquid chromatography.

Purity of Chiral Derivatization Reagent or Chiral Selector

For the chiral derivatization method, there is one point which necessitates careful interpretations of the results. When the enantiomeric mixture of (+)-A and (–)-A are derivatized with the chiral derivatizing reagent of (+)-B, it often includes (–)-B as a chiral impurity. If the reagent B is 100% optically pure, two diastereomers (+)-A-(+)-B (I) and (–)-A-(+)-B (II) are formed. If reagent B is not optically pure, additional diastereomers (+)-A-(–)-B (III) and (–)-A-(–)-B (IV) are formed.

Reaction products

The enantiomers of A to be separated and determined as their diastereomeric derivatives (I and II) can be resolved as the respective peaks on an achiral stationary phase. However, the peaks of the products

III and IV produced with (–)-B overlap with the peaks of II and I, respectively, on achiral stationary phases, because II and III, and I and IV are enantiomeric pairs. Therefore, if the optical purity of the derivatization reagent is not known or not taken into consideration, the optical purity of the target compound will not be determined accurately. Further, this is the case when the separation of enantiomers is carried out by the use of chiral additives to the eluent on achiral stationary phases.

In contrast, direct resolution of enantiomers using chiral stationary phases does not have the drawbacks described above. We can easily determine 0.1% or 0.05% of the antipode using chiral stationary phases.

Indirect Methods

The indirect method, involving reaction with a homochiral reagent, is an efficient technique for the separation of many enantiomers. It is essential that the chiral derivatization proceeds completely in both enantiomers, and that racemization does not occur. The indirect methods are unsuitable for analysis of enantiomers in a standard sample and pharmaceutical preparations, because the low amount of the antipode level should be determined, and are unsuitable for preparative purposes. However, they are suitable for trace analysis of enantiomers in complex matrices such as biological samples and environmental samples because of the introduction of highly sensitive tags. These include UV-visible, fluorescent and electrochemical tags. Fluorescence derivatization is the most effective to determine the target compound in complex matrices in terms of sensitivity and/or selectivity. **Table 1** shows the fluorescence derivatization reagents (**Figures 1** and **2**) used for the separation of enantiomers bearing amino, keto, hydroxyl and carboxyl groups.

Direct Methods

Direct methods using chiral mobile-phase additives can separate many enantiomers by addition of chiral selectors to an eluent on achiral stationary phases. However, for preparative applications, the additives must be removed. Separations on chiral stationary phases can be used for both analytical and preparative purposes. At the present time, the trend is to use chiral stationary phases for the separation of enantiomers by liquid chromatography whenever possible.

Table 1 Fluorescence derivatizing reagents used for the separation of enantiomers

Reagent	Enantiomer	Separation mode
OPA + N-protected L-cystein	Amino acids, amino alcohols, baclofen, tranlycypromine	Reversed-phase
FLEC	Amino acids, methamphetamine, ephedrine, atenolol	Reversed-phase
DANE	Amino acids, ibuprofen, indoprofen, naproxen, loxoprofen	Normal-phase
NEIC	Propranolol, nadolol, prenylamine, betaxolol, acebutolol	Reversed-phase and normal-phase
Methyl-BNCC	Hydroxyls, β -hydroxy acids, propranolol, penbutolol	Normal-phase
NBD-Apy	N-acetyl amino acids, antiinflammatory drugs	Reversed-phase
NBD-Pro-COCl	Alcohols, amine	Reversed-phase
NBD-ProCZ	Ketones	Reversed-phase
NBD-PyNCS	Amines, β -blockers, amino acids, peptides	Reversed-phase
FLOPA	Ibuprofen, α -phenylcyclopentyl acid	Reversed-phase and normal-phase
FLOP-Cl	Amino acids, peptides	Reversed-phase and normal-phase
MNE-OTf	α -Methoxyphenylacetic acid, propranolol	Reversed-phase

See Figures 1 and 2 for definitions of abbreviations.

Chiral Stationary Phases

Many chiral selectors are adsorbed or immobilized covalently on to liquid chromatography supports. The chiral stationary phases obtained are classified into two types with respect to their general structure. One type is based on synthetic or natural polymers, which are totally or intrinsically chiral; the other type is based on a chiral selector of low molecular weight. Chiral stationary phases can be further classified into five types based on the solute and chiral stationary-phase interactions:

- Type I: the diastereomeric complexes of the solute and chiral stationary phase are formed by attractive interactions such as hydrogen-bonding, π - π , dipole stacking, etc., between the solute and chiral stationary phase.

- Type II: the primary mechanism for the formation of the solute and chiral stationary phase complex is through attractive interactions, but inclusion complexes also play an important role.
- Type III: the solute enters into chiral cavities within the chiral stationary phase to form inclusion complexes.
- Type IV: the solute is a part of a diastereomeric metal complex; this is called chiral ligand exchange chromatography.
- Type V: the chiral stationary phase is a protein and the solute and chiral stationary phase complexes are based on combinations of hydrophobic, electrostatic and hydrogen-bonding interactions.

Table 2 shows commercially available chiral stationary phases which are classified into these five types.

**Figure 1** Structure of reagents (see Table 1).

Figure 2 Structure of reagents (see Table 1).

Type I Chiral Stationary Phases

These stationary phases were based on aromatic π -acid (3,5-dinitrobenzene) and π -base (a naphthalene moiety) derivatives. In addition to π - π interaction sites, they have hydrogen-bonding and dipole-dipole interaction sites provided by an amide, urea or ester moiety. By nuclear magnetic resonance measurements in solution, three interactions are proposed to occur in the more favoured diastereomeric complex between an *N*-(3,5-dinitrobenzoyl)- α -amino amide and an *N*-(2-naphthyl)- α -amino ester: a π -donor-acceptor interaction and two hydrogen-bonding interactions, as shown in **Figure 3**. In the development of these stationary phases, the reciprocity concept was introduced as follows: if optically active A resolves the enantiomers B, then optically active B resolves the enantiomers of A. As a result, π -acid and π -base compounds have been separated using chiral stationary phases based on π -base and π -acid derivatives. Since a combination of simultaneous π - π and hydro-

gen-bonding interactions in the nonpolar solvent used as the mobile phase play an important role in chiral recognition, as described above, these stationary phases are mainly used in the normal-phase mode, although it is possible to separate some enantiomers in the reversed-phase mode.

Recently, chiral stationary phases based on the macrocyclic antibiotics, vancomycin and teicoplanin, have been developed. These stationary phases can separate many enantiomers in both normal- and reversed-phase modes.

Type II Chiral Stationary Phases

Underivatized saccharides such as cellulose and starch have been used as chiral stationary phases. Cellulose, which contains *c.* 200 glucose units (micro-crystalline cellulose), has been extensively used for the chiral resolution of highly polar compounds such as amino acids, amino acid derivatives and diaminodicarboxylic acids. The chiral recognition ability

Table 2 Chiral stationary phases for liquid chromatography

Type	Ligand	Trade name
Type I	<i>N</i> -(3,5-Dinitrobenzoyl)-D-, <i>N</i> -(3,5-Dinitrobenzoyl)-L-phenylglycine	D-,L-Phenylglycine
	<i>N</i> -(3,5-Dinitrobenzoyl)-D-, <i>N</i> -(3,5-Dinitrobenzoyl)-L-leucine	D-,L-Leucine
	Naphthyl-D-, naphthyl-L-alanine	D-, L-Naphthylalanine
	Naphthyl-D-, naphthyl-L-leucine	D-,L-Naphthylleucine
	<i>N</i> -(3,5-Dinitrobenzoyl)-(R)-1-naphthylglycine	Sumichiral OA-2500
	<i>N</i> -(3,5-Dinitrobenzoyl)-aminocarbonyl-L-valine	Sumichiral OA-3100
	<i>N</i> -[(S)-(1-Naphthyl) ethylaminocarbonyl]-L-valine	Sumichiral OA-4000
	(R)-, (S)-1-Naphthylethylamine	LC-(R)-, LC-(S)-Naphthyl urea
	Teicoplanin	Chirobiotic T
	Vancomycin	Chirobiotic V
Type II	Microcrystalline cellulose triacetate	Chiralcel CA-1
		Cellulose triacetate
	Cellulose <i>tris</i> (4-methylbenzoate)	Chiralcel OJ, OJ-R
	Cellulose tribenzoate	Chiralcel OB, OB-H
	Cellulose triacetate	Chiralcel OA
	Cellulose tricinnamate	Chiralcel OK
	Cellulose <i>tris</i> (3,5-dimethylphenylcarbamate)	Chiralcel OD, OD-H, OD-R
	Cellulose <i>tris</i> -phenylcarbamate	Chiralcel OC
	Cellulose <i>tris</i> (4-methylphenylcarbamate)	Chiralcel OG
	Cellulose <i>tris</i> (4-chlorophenylcarbamate)	Chiralcel OF
	Amylose <i>tris</i> (3,5-dimethylphenylcarbamate)	Chiralpak AD
	Amylose <i>tris</i> [(S)-1-phenylethylcarbamate]	Chiralpak AS
	Poly- <i>N</i> -acryloyl-(S)-phenylalanine ethylester	ChiraSpher
	(+)-Poly(triphenylmethyl methacrylate)	Chiralpak OT(+)
	(+)-Poly(diphenyl-2-pyridylmethyl methacrylate)	Chiralpak OP(+)
Type III	2,2'-Diphenyl-1,1'-binaphthol derivatives of 18-crown-6	Crownpak CR(+)
		Crownpak CR(-)
	α -, β -, γ -Cyclodextrin	Cyclobond III, I, II
	β -, γ -Cyclodextrin	ChiraDex, ChiraDex Gamma
	β -Cyclodextrin derivatives	Cyclobond I Ac, SP, RSP, SN, RN, DMP, PT ^a ; Ultron ES-PhCD ^b ; Nucleosil β -PM ^c
	α -, γ -Cyclodextrin derivatives	Cyclobond III Ac, II Ac
Type IV	L-Hydroxyproline	Nucleosil Chiral-1
	2-Amino-1,2-diphenylethanol	Chiralpak WE
	<i>N,S</i> -Dioctyl-D-penicillamine	Sumichiral OA-5000
Type V	Bovine serum albumin	Resolvosil BSA-7, BSA-7PX
		Ultron ES-BSA
		Chiral-BSA
	Human serum albumin	Chiral-HSA
		Chiral-HSA
	α_1 -Acid glycoprotein	Chiral-AGP
	Ovomucoid	Ultron ES-OVM
	Avidin	Bioptric AV-1
	Cellulase	Chiral-CBH
	Pepsin	Ultron ES-Pepsin

^a Ac, Acetate; SP, (S)-2-hydroxypropyl ether; RSP, racemic 2-hydroxypropyl ether; SN, (S)-naphthylethylcarbamate; RN, (R)-naphthylethylcarbamate; DMP, 2,6-dimethylphenylcarbamate; PT, *para*-toluoyl ester.

^b PhCD, Phenylcarbamate.

^c β -PM, Permethylate.

of the cellulose is based on the microcrystallinity because, when treated with dilute alkali, cellulose loses its chiral recognition ability, resulting in a stable amorphous form.

It was found that microcrystalline cellulose triacetate preserved microcrystallinity and had excellent chiral recognition ability. In contrast, microcrystalline cellulose triacetate precipitated from a solution

Figure 3 The more favoured diastereomeric complex between an *N*-(3,5-dinitrobenzoyl)- α -amino amide and an *N*-(2-naphthyl)- α -amino ester. A π -donor-acceptor interaction and two hydrogen-bonding interactions are indicated by arrows. (Reproduced with permission from Pirkle WH and Pochapsky TC (1987) *Advances in Chromatography*, vol. 27, p. 116. New York: Marcel Dekker.)

has another morphology, and different chiral recognition properties, compared with microcrystalline cellulose triacetate. The chiral stationary phases based on the cellulose triacetate precipitated from a solution are prepared by coating the polymer on a silica gel matrix. Many chiral stationary phases prepared by this technique are commercially available as triacetate, tribenzoate, trisphenylcarbamate, tribenzyl ether and tricinnamate derivatives of cellulose.

Chiral stationary phases based on cellulose and amylose derivatives could separate 78% of racemates examined. However, the disadvantage of stationary phases based on the cellulose and amylose derivatives coated on silica gels is the restriction of the eluents used; the coated polymer is soluble in some eluents and removed. Polysaccharide derivatives chemically bound to silica gel overcome this problem. The coated and the chemically bound polymers showed different chiral recognition properties.

With regard to the chiral recognition mechanism, the interaction of the solute and the chiral stationary phase based on cellulose phenylcarbamate derivatives has been investigated by computational chemistry and nuclear magnetic resonance measurements of the complex. It was found that π - π and hydrogen-bonding interactions play an important role in chiral recognition of the solute.

Type III Chiral Stationary Phases

Type III chiral stationary phases include cyclodextrin (CD), polymethacrylate and crown ether stationary phases. The solute enters into chiral cavities to form inclusion complexes and the relative stability constants of the resulting diastereomeric complexes are different. The cavities of CD and polymethacrylate are hydrophobic, while those of crown ethers are hydrophilic.

α -, β - and γ -CD are cyclic oligosaccharides containing 6, 7 and 8 β -1, 4-D-glucoside units, respectively. Because an aromatic portion of a molecule can enter into the chiral cavity, solutes having an aromatic moiety at, or adjacent to, the chiral centre are well resolved. Acetyl, hydroxypropyl, naphthylethyl carbamate and phenyl carbamate derivatives of CDs have been prepared and used for chiral resolution of many solutes which cannot be separated using native CDs. Chiral stationary phases based on CDs and derivatized CDs have been predominantly used in reversed-phase mode.

Chiral stationary phases based on polymethacrylate have been prepared using a chiral monomer such as (*S*)-acryloylphenylalanine, and achiral monomers such as triphenylmethyl methacrylate and diphenyl-2-pyridylmethyl methacrylate together with chiral cation catalysts. In normal-phase mode, chiral stationary phases based on these polymers can separate many racemic solutes that are difficult to resolve by other methods because of a lack of functionality.

Crown ethers, which are synthetic macrocyclic polyethers, can form selective complexes with various cations. Chiral crown ethers covalently bound or adsorbed on to silica supports can separate enantiomeric ammonium compounds such as amino acid esters, amines and amino alcohols. The multiple hydrogen-bonding interactions between the ammonium group and the ether oxygens play an important role in the chiral recognition.

Type IV Chiral Stationary Phases

Chiral ligand exchange chromatography is based on the formation of diastereomeric ternary complexes that involve a transition metal ion (M), chiral ligand (L), and the enantiomers of the racemic solute (R and S). Of all the transition metals examined [Cu(II), Ni(II), Zn(II), Hg(II), Co(III), Fe(III), etc.], Cu(II) forms the most stable complexes, and cyclic amino acids such as L-proline and L-hydroxyproline are the best chiral selectors, when bound to a polymer or silica support. The diastereomeric mixed chelate complexes formed in this system are represented by the formulas L-M-R and L-M-S. When these

complexes have different stabilities, the less stable complex is eluted first, and the enantiomeric solutes are separated. The enantiomers resolved include amino acids, amino acid derivatives, 2-amino alcohols, barbiturates and hydantoins.

Type V Chiral Stationary Phases

Chiral stationary phases based on a protein are of special interest because of their unique properties of stereoselectivity and because they are suited for separating a wide range of enantiomeric mixtures. Protein-based stationary phases so far developed have included albumins such as bovine and human serum albumin, enzymes such as trypsin, α -chymotrypsin, lysozyme and pepsin, and glycoproteins such as α_1 -acid glycoprotein from human or bovine serum, cellobiohydrolase I from the fungus *Trichoderma reesei*, ovomucoid (in fact, ovoglycoprotein), avidin

and ovotransferrin from egg whites, and flavoprotein (riboflavin-binding protein) from egg whites and yolks. The advantages of protein-based stationary phases generally include the use in reversed-phase mode, enantioselectivity for a wide range of compounds and direct analysis without derivatization. The disadvantages are low capacity, lack of column ruggedness and limited understanding of the chiral recognition mechanism. These stationary phases are mainly used for analytical purposes.

With regard to the chiral recognition mechanism, hydrophobic, electrostatic and hydrogen-bonding interactions take place between the chiral stationary phase and the solute.

Chiral Mobile Phase Additives

There are no fundamental differences between the techniques using chiral stationary phases and chiral

Table 3 Chiral selectors used as mobile-phase additives

Chiral selector	Enantiomers	Stationary phase
Metal complex		
L- or D-Proline + Cu(II), L-Phenylalanine + Cu(II), N-Methyl-L-phenylalanine + Cu(II), N,N-Dimethyl-L-phenylalanine + Cu(II), (R, R)-Tartaric acid mono-1-octylamide + Cu(II)	Amino acids	Cation exchanger, ODS, OS
L-Propyl-n-octylamide + Ni(II), L-Proline + Cu(II), L-Arginine + Cu(II), L-Histidine + Cu(II)	Dansyl amino acids	ODS, OS

mobile phase additives. This means that all chiral selectors covalently bound to supports can be used for the separation of enantiomers by addition to the mobile phase. With chiral mobile phase additive techniques, there are at least two possible mechanisms; one is that the chiral mobile phase additive and the enantiomers may form diastereomers in the mobile phase. Another is that the stationary phase may be coated with the chiral mobile phase additive, resulting in diastereomeric interactions with the enantiomeric pairs during chromatography. It is thought that both mechanisms occur depending on both the stationary and mobile phases used.

The techniques using chiral mobile phase additives can be divided into three categories: metal complexation used in chiral ligand exchange chromatography, the use of various uncharged additives, and the ion-pairing techniques used for charged analytes. **Table 3** shows chiral selectors used as mobile phase additives.

Molecular Imprints as Stationary Phases

M. Kempe, Lund University, Lund, Sweden

Copyright © 2000 Academic Press

In 1949, Frank Dickey published what can be considered the first paper on a molecularly imprinted synthetic material. The work was inspired by the theories of Dickey's mentor Linus Pauling, who had suggested that the primary structures of all polypeptides constituting the antibodies are the same and that the diversity originates from folding directed by physical contact with the antigens. Even if Pauling's hypothesis on antibodies later turned out to be incorrect, his ideas laid the foundation for the concept of molecular imprinting. Consistent with these early studies, molecular imprinting can be defined as a method in which the selectivity of a material for a chosen molecule is induced by the presence of the molecule during the preparation, assembling or rearrangement of the material.

Dickey's studies were followed by several other investigations in the same direction, but it was not

until the 1970s that the field of molecular imprinting started to mature to its present form. Wulff introduced a new approach that allowed the introduction of functional groups at defined positions in synthetic network polymers. This approach is often referred to as covalent molecular imprinting, to distinguish it from the noncovalent approach developed by Mosbach and his co-workers in the early 1980s.

The field of molecular imprinting is growing rapidly. Molecularly imprinted polymers (MIPs) have found application as stationary phases for chiral separations and solid-phase extractions, as synthetic antibodies in competitive ligand-binding assays, as recognition elements in sensors and as catalysts of chemical reactions. The concepts of molecular imprinting will be described briefly here. For a more detailed description of the imprinting principle and the preparation of molecularly imprinted polymers, see 'Affinity Separation: Imprint Polymers' in this encyclopedia. The remainder of this paper focuses on the use of molecularly imprinted polymers as chiral stationary phases (CSPs).

The Concepts of Molecular Imprinting

Molecular imprinting, sometimes referred to as template polymerization, is a technique for preparing synthetic polymers of predetermined selectivity. Receptor-like binding sites are tailor-made *in situ* by the copolymerization of cross-linkers and functional monomers, which are interacting covalently or noncovalently with print molecules (or templates). After polymerization, the print molecules are removed from the polymer, either by extraction or by chemical cleavage, leaving recognition sites complementary to the print molecules in the shape and positioning of functional groups. The polymer is subsequently able to rebind the print molecules. The noncovalent approach of molecular imprinting is exemplified in Figure 1.

The association/dissociation kinetics of noncovalent MIPs is in general faster than is observed with polymers prepared by the covalent approach. For this reason, the former polymers are more attract-

ive as stationary phases for chromatography. Even if several examples of covalently imprinted stationary phases have been reported, it was not until the development of the noncovalent approach that the technique became competitive for the preparation of CSPs. This review will therefore focus on noncovalent molecular imprinting. The covalent approach has been covered in several excellent reviews by Wulff.

Even if the general understanding has been that the selectivity of MIPs is due to the formation of specific recognition sites complementary to the print molecules, early critics of the technique argued that the recognition could come from binding to print molecules entrapped in the highly cross-linked polymers. A small percentage of the print molecules are inaccessible and remain in the polymer network after extraction (normally less than 1%). However, this was ruled out as the cause of the selectivity by experiments showing that a polymer containing covalently bound print molecules did not exhibit any selective binding of the print molecule.

Figure 1 Schematic representation of the concept of noncovalent molecular imprinting. Functional monomers, in this case methacrylic acid, interact with the print molecule, Z-Glu-OH. Cross-linker is added and the polymerization is initiated. The interactions are maintained in the resulting polymer. The print molecule is removed from the polymer by extraction, leaving a specific recognition site complementary to the print molecule in shape and positioning of the functional groups. The polymer has attained a memory of the print molecule and is able selectively to rebind it.

Molecular imprinting produce recognition sites with a distribution of binding strengths; the sites are heterogeneous. Some sites have a highly selective affinity for the template, whereas others are less selective. When used for chromatographic applications, the heterogeneity is reflected in band broadening and asymmetric peaks.

Chiral Separations

Initial studies on noncovalent MIPs focused mainly on the preparation of materials selective for amino acid derivatives. The polymers possessed not only a selectivity for the amino acid used as the print molecule, but were also found to be enantioselective; the enantiomer present during the polymerization was preferentially bound. These findings, together with observations that the polymers were mechanically and chemically stable, made them attractive as CSPs and spurred further research.

The imprinting effects of MIPs prepared with optically active compounds as the print molecules are readily demonstrated by chromatographic evaluation. For example, when the L-enantiomer of an amino acid derivative is used as the print species, a column packed with the resulting polymer will retain the L-enantiomer longer than the D-enantiomer, and vice versa when the D-enantiomer is used as the print molecule. Reference polymers prepared with the racemate or without print molecule will not be able to resolve the racemate. A stereoselective memory is hence induced in the polymers by the print molecules.

Molecularly imprinted CSPs have been prepared for applications in high performance liquid chromatography (HPLC), thin-layer chromatography (TLC), capillary electrophoresis (CE) and capillary electrochromatography (CEC). CSPs for HPLC are by far the most studied.

HPLC

A large number of chiral amino acids and peptides have been imprinted. Several MIPs selective for pharmaceuticals have also been described. The most widely used method has been bulk polymerization followed by grinding, sieving and packing into HPLC columns. Alternatively, the polymers can be prepared by any of the methods discussed in 'Affinity Separation: Imprint Polymers' in this encyclopedia. Some examples of MIP CSPs are shown in Table 1.

The selectivities are in many cases comparable to those of commercially available CSPs. For example, a separation factor (α) of 17.8 was found for the separation of the two enantiomers of a dipeptide on *poly*(methacrylic acid-*co*-EDMA) (EDMA = ethy-

lene glycol dimethacrylate) imprinted with one of the enantiomers (Figure 2).

The specificity and selectivity of MIPs can be fine-tuned by careful choice of monomers and solvent, and by optimizing the molar ratios of the components in the polymerization mixture. The recognition relies on multiple interaction points. The more functionalized the print molecule is, the more interactions are possible. An example of a highly selective polymer is *poly*(4-vinylpyridine-*co*-EDMA) imprinted with Z-L-aspartic acid (1). The chromatogram in Figure 3A shows the separation of racemic Z-aspartic acid on this CSP. Aspartic acid and glutamic acid differ by only one methylene unit, but despite this small difference, the Z-aspartic acid-imprinted CSP was not able to resolve racemic Z-glutamic acid (2) (Figure 3B). The side chain of Z-L-glutamic acid cannot be accommodated into the recognition site in a way that allows specific interaction between the carboxy functionality and the positioned pyridine group of the polymer. The same type of polymer, imprinted with Z-L-glutamic acid, was able to resolve racemic Z-glutamic acid, but not racemic Z-aspartic acid. Similar observations have been done on *poly*(methacrylic acid-*co*-EDMA) imprinted with these print molecules.

Polymers imprinted with Z-L-phenylalanine (3a) were able to separate racemic Z-phenylalanine efficiently (Table 2). Racemic Z-alanine (3b) could also be separated on these CSPs, even if lower separation factors were observed. When the amino-group of the racemate was protected with *tert*-butoxycarbonyl (Boc) (3c) or 9-fluorenylmethoxycarbonyl (Fmoc) (3d), the separations were poorer than with the racemate of the print molecule, which was protected with benzyloxycarbonyl (Z). In contrast to the CSPs described above, which were unable to separate the racemate of a molecule which only differed from the

print molecule by one methylene unit, these polymers were able to separate all of the tested structurally related racemates, even if the separations were not as good as with the print molecule and its optical antipode. This shows that the polymer recognizes both

the amino-protecting group and the side chain, but that an exact fit is not necessary for enantioseparation in these cases.

polymer was able to resolve not only racemic timolol (4), but also racemic propanolol (5). In contrast to this, a timolol-imprinted polymer prepared with itaconic acid as the functional monomer instead of methacrylic acid could only resolve racemic timolol out of a number of racemates of structurally related β -blockers (Figure 4). This clearly demonstrates that the selectivity of MIPs can be highly dependent on the functional monomer used.

A comparison of six different CSPs, all imprinted with the same print molecule (Z-L-phenylalanine), confirms that the choice of monomers is important for the selectivity of the resulting polymers (Table 3). The selectivity of EDMA-based polymers was higher when vinylpyridines were used, either alone or together with methacrylic acid, than when methacrylic acid was used alone. Methacrylic acid interacts with the print molecule through hydrogen bonds. The beneficial effect of vinylpyridine is attributed to strong ionic interactions between the carboxy groups of the print molecule and the pyridinyl groups. The polymer prepared with acrylamide also showed a higher selectivity than the one prepared with methacrylic acid. Acrylamide forms strong hydrogen bonds even in a polar solvent such as acetonitrile.

It is noteworthy that the load capacity and the resolving capability increased when the trifunctional cross-linker pentaerythritol triacrylate (PETRA) was used instead of EDMA. The same features have been seen with polymers prepared with trimethylolpropane trimethacrylate (TRIM), another trifunctional cross-linker. *Poly(methacrylic acid-co-TRIM)* imprinted with a dipeptide was able to resolve 1 mg of the racemate with almost baseline separation (analytical column: 4.6×250 mm) (Figure 5).

(S)-Naproxen (6), a nonsteroidal anti-inflammatory drug, has been imprinted in *poly(4-vinylpyridine-co-EDMA)* by two different approaches. Bulk polymerization followed by grinding and sieving resulted in highly irregular particles and a two-step swelling and polymerization method gave uniformly sized beads. Both materials, used in the chromatographic mode, were able to separate naproxen from the related ibuprofen (7) and ketoprofen (8). The polymers were also able to resolve racemic naproxen, but not the racemates of ibuprofen and ketoprofen (Figure 6). Even

if comparisons of the two chromatograms cannot be done because of differing flow rates, it is not obvious that the chromatographic efficiency was better with the uniformly sized beads (Figure 6B) than with the irregular particles (Figure 6A). This may be due to impairment on the selectivity by water interfering with the monomer–print molecule complex, since water was used as the suspension medium in the two-step swelling and polymerization method.

In general, the polymerizations in noncovalent molecular imprinting have to be done in nonaqueous solutions to prevent water molecules from interfering with the interactions between the monomers and the templates, as previously discussed. Several reports, however, show that the chromatography can be performed efficiently with buffered aqueous eluents.

An approach has been developed which allows both the imprinting and the chiral separation of free amino acids to be carried out in aqueous solutions. The recognition was based on metal coordination–chelation interactions using *N*-(4-vinylbenzyl)imino-diacetic acid as the functional monomer. The method worked best for aromatic amino acids (Figure 7).

TLC

MIPs selective for phenylalanine anilide have been evaluated as stationary phases in TLC. Glass backing plates were coated with mixtures of finely ground MIP particles and binders. The plates showed preferential retardation of the enantiomer used as the print molecule (Figure 8). The R_F values of both enantiomers on nonimprinted polymers were higher than those observed on the imprinted polymers. The separations suffered from spot broadening, which was attributed to the heterogeneity of the recognition sites.

Figure 7 Separation of 17 μg of racemic phenylalanine on $\text{poly}(\text{Cu}(\text{II})[N-(4\text{-vinylbenzyl})]\text{iminodiacetate-co-EDMA})$ grafted to silica particles (4.6 \times 50 mm column). The polymer was imprinted with D-phenylalanine. Isocratic elution at 1 mL min^{-1} , 50°C with 1.5 mmol L^{-1} glycine in water. (Adapted from Vidyasankar S, Ru M and Arnold FH (1997) *Journal of Chromatography A* 775: 51–63, © 1997, with permission from Elsevier Science, UK.)

The technique is attractive because it is simple, fast and allows multiple analyses in the same run.

CE and CEC

Chiral separation by CE and CEC is achieved using a chiral selector which is either free in the mobile phase or immobilized to the stationary phase. MIPs can be used as the selector in both approaches. Molecularly imprinted capillary columns have been prepared by various approaches:

1. packing performed MIP particles into the capillaries
2. dispersion polymerization *in situ* in the capillaries
3. incorporating preformed MIP particles into polyacrylamide gels
4. *in situ* polymerization on the inner walls of the capillaries
5. filling the capillaries with a monolithic polymer with continuous pores by *in situ* polymerization.

Figure 9A shows the separation of racemic propanolol by CEC on a capillary column filled with $\text{poly}(\text{methacrylic acid-co-TRIM})$, polymerized *in situ* using (*R*)-propanolol as the print molecule. Several attractive features make this system look promising for the future: very low consumption of the print molecule (in this case only 10 μg), fast preparation of the capillaries (3 h) and fast separation (less than 2 min). In Figure 9B, MIP particles selective for (*S*)-propanolol were added to the mobile phase in a CE separation.

Future Developments

Molecular imprinting is a technique which has great potential. MIPs have found many applications, and many more are likely to be developed. One of the first applications investigated was CSPs, the subject of this chapter. A number of polymer systems have been developed and these have been used to imprint different classes of compounds.

To be able to attribute the binding of an MIP to an imprinting effect it is of the utmost importance to show that specific recognition sites were formed due to the presence of the print molecules during the polymerization. This is done by comparison with appropriate reference polymers. Polymers prepared without print molecules are not always the best choice, since the physical properties (surface area,

Figure 8 Separation of L- and D-phenylalanine anilide on TLC plates covered with $\text{poly}(\text{methacrylic acid-co-EDMA})$ imprinted with (A) L-phenylalanine anilide; (B) D-phenylalanine anilide and (C) no print molecule. Elution with $\text{CH}_3\text{CN-HOAc}$ (99 : 5). Separation of racemic propranolol using 0.05% (w/v) *poly*(*N*-acryloylalanine-*co*-EDMA) particles imprinted with (*S*)-propranolol as a chiral additive in the background electrolyte ($100\ \mu\text{m} \times 470\ \text{mm}$ capillary column). The sample was injected by a 3 s pressure injection and was separated at a constant voltage of 15 kV. The electrolyte was $5\ \text{mmol L}^{-1}$ phosphate buffer, pH 7.0. Detection at 210 nm. Temperature: 25°C . (Adapted from Walshe M, Garcia E, Howarth J, Smyth MR and Kelly MT (1997) *Analytical Communications* 34: 119–122, © 1997, with permission from the Royal Society of Chemistry, UK.)

porosity, etc.) of these polymers are often different from those of imprinted polymers. Reference polymers prepared with the optical antipode or a racemic mixture as the print species are preferred. The selectivity will be reversed when using the optical antipode, and a racemic mixture will give a polymer incapable of separating the two enantiomers (unless the monomers are chiral).

The goal of an endeavour involving chromatographic separation is to achieve the best possible performance with respect to selectivity, resolution, load capacity and analysis time. Much research effort on MIPs has therefore focused on improving the chromatographic performance. The use of monodisperse spherical beads instead of irregular particles improves the efficiency and investigations in this direction with MIPs have already given promising results. Another issue that needs to be investigated further is the heterogeneity of the binding sites. A more homogeneous population of sites would improve the chromatographic performance. The load capacity of MIPs has been shown to be improved by the use of trifunctional cross-linkers such as TRIM

and PETRA instead of the bifunctional EDMA. These findings look promising for future developments of MIPs for semipreparative and preparative purifications.

Molecular imprinting is an expanding area attracting an increasing number of scientists, in both industry and academia. This is evidenced by the fact that three-quarters of all papers on molecular imprinting were published during the last decade and one-third during 1996–1997. The rapid development of this technique is likely to result in many breakthroughs within the next few years.

Protein Stationary Phases

J. Haginaka, Mukogawa Women's University,
Nishinomiya, Japan

Copyright © 2000 Academic Press

In the early 1950s, it was reported that the binding of the enantiomers of an anionic azo-dye to bovine serum albumin (BSA) or human serum albumin (HSA) was different. Further, it was reported that L-tryptophan was bound to serum albumin (bovine mercaptoalbumin) more strongly than the D-form. These studies clearly indicated the possibility of enantioselective binding of ligands to proteins. In 1973, BSA-Sepharose was used for the separation of tryptophan enantiomers; this is the first report on the use of a protein stationary phase for chiral resolution purposes. With this stationary phase, D- and L-tryptophan were clearly resolved, and the D-form was eluted first, as shown in the previous binding studies in solution. In the following years, high performance liquid chromatography (HPLC) chiral stationary phases based on a protein were developed and used to separate a variety of enantiomers. HPLC chiral stationary phases based on a protein are of special interest because of their unique properties of stereoselectivity and because they are suited for separating a wide range of enantiomeric mixtures. Protein-based stationary phases developed so far have included albumins such as BSA and HSA, enzymes such as trypsin, α -chymotrypsin, lysozyme and pepsin, and glycoproteins such as α_1 -acid glycoprotein (AGP) from human or bovine serum, cellobiohydrolase I (CBH I), ovomucoid (in fact, ovoglycoprotein), avidin, ovotransferrin and flavoprotein (riboflavin-binding protein). The physical properties of these proteins are shown in Table 1. Chiral stationary

phases based on BSA, HSA, pepsin, AGP, CBH I, ovomucoid and avidin are now commercially available. Among those, AGP and ovomucoid-based stationary phases can separate a wide range of weakly acidic, weakly basic and neutral racemates.

The advantages of protein-based stationary phases generally include the use of an aqueous mobile phase, enantioselectivity for a wide range of compounds and direct analysis without derivatization. The disadvantages included low capacity, lack of ruggedness and limited understanding of the chiral recognition mechanism. Thus, the protein-based stationary phases are useful for analytical purposes, but are not generally applicable to preparative isolation. To stabilize the protein-based stationary phases, chemical modification of the side chains of the amino acids in the protein has been tried. Further, chiral stationary phases based on a protein fragment or protein domain have been prepared. These can be of higher capacity because only the active protein mass is used. Also, it is possible to understand the chiral recognition sites of protein-based stationary phases by investigating whether or not independent chiral binding sites exist on each fragment or domain.

This article deals with the preparation of HPLC chiral stationary phases based on a protein, their chiral recognition properties and the chiral recognition mechanisms of these stationary phases.

Preparation of HPLC Chiral Stationary Phases Based on a Protein

Generally, a protein is bound to derivatized silica gels. The disadvantage of silica-based stationary

Table 1 Physical properties of proteins

Ovotransferrin	77	2.6	6.1	Egg white
Flavoprotein	32–36	14	4	Egg white or yolk

phases is that the eluent pH is limited to the ranges 2–8. However, in a strong acidic or alkaline solution, a protein sometimes suffers from denaturation. The separation of enantiomers on a protein-based stationary phase is generally attained using an eluent whose pH is between 3 and 8. Thus, the limitation of eluent pH ranges originated from silica-based materials is no problem for the use of protein-based stationary phases. **Figure 1** shows the typical preparation method for protein-based HPLC chiral stationary phases; in part A the method includes activation of porous aminopropylsilica gels by *N,N'*-disuccinimidylcarbonate (DSC), binding of a protein and blocking of the activated amino groups. In this case, a side chain amino group(s) of a protein such as lysine and arginine and/or an *N*-terminal amino group could be used for binding the protein to the activated gel. On the other hand, using water-soluble carbodiimide and *N*-hydroxysulfosuccinimide (HSSI), the carboxyl group of a protein can be bound to aminopropylsilica gels, as shown in **Figure 1B**.

Further, proteins can be bound to aminopropylsilica gels using glutaraldehyde as a cross-linker, resulting in cross-linking by Schiff-base formation. The resulted imino functions are reduced by using sodium cyanoborohydride. Glycerylpropylsilica gels activated with 1,1'-carbonyldiimidazole have been used for the preparation of chiral stationary phases. According to the two methods described above, an amino group of a protein is used to bind to the derivatized silica gels. In addition, a protein can be physically adsorbed on to porous silica gels. The disadvantage of the adsorption method is that the

adsorbed protein can be eluted, and it is better to bind a protein covalently to the base materials in order to avoid losses. The chiral recognition properties of a bound or adsorbed protein may be different from those of the protein in solution because of blocking of functional groups and/or conformational changes. The bound protein is often more stable to the changes of eluent pH and eluent composition compared to the protein in solution.

Retention and Enantioselectivity of Solutes on Protein-based Stationary Phases, and Optimization of Resolution

Table 2 shows the influence of eluent pH on the retention and enantioselectivity of various solutes on AGP-based chiral stationary phases. The retention factor of a basic solute, metoprolol, increased with an increase in the eluent pH. The decrease in the retention factor of an acidic solute, 2-phenoxypropionic acid, is ascribable to ion exclusion in addition to ionic repulsion between the carboxyl group of the 2-phenoxypropionic acid and the negatively charged AGP with an increase in eluent pH. The retention of basic solutes should be due to electrostatic interactions with the positively charged solutes and the negatively charged protein, in addition to hydrophobic interactions. Although the retention factor of an uncharged solute (ethotoin, hexobarbital) shows almost no pH dependence, a slight increase is observed with increasing eluent pH. This increase might be

Figure 1 Synthesis scheme for the preparation of protein-based stationary phases: (A) via an amino group of a protein; (B) via a carboxyl group of a protein.

due to changes in the binding properties of the protein resulting from conformational changes. Table 3 shows the influence of the 2-propanol content on

retention and enantioselectivity of various solutes on AGP-based chiral stationary phases. With an increase in the 2-propanol content, the retention and

enantioselectivity of solutes are decreased. These results suggest that hydrophobic and electrostatic interactions play an important role in the retention and enantioselectivity of racemic solutes on AGP-based columns. Further, the hydrogen bonding properties of the organic modifier influence enantioselectivity to a large extent. As shown in **Figure 2**, verapamil enantiomers are not resolved on the AGP-based column using 1-propanol as an organic modifier, but are resolved using acetonitrile.

Similar retentive and enantioselective properties are observed with other protein-based stationary

phases. As described above, hydrophobic, electrostatic and hydrogen bonding interactions play an important role in chiral recognition of solutes on these phases. Thus, enantioseparations of solutes can be optimized by changing eluent pH, and the type and content of the uncharged organic modifier. Sometimes, charged modifiers such as *N,N*-dimethyloctylamine and octanoic acid are used for the enantioseparation of a charged solute. **Figure 3** shows a scheme for the optimization procedure for ovomucoid-based stationary phases.

Albumin-based Stationary Phases

BSA and HSA are closely related proteins and, consequently, the chromatographic properties of the chiral stationary phases based on these proteins are similar. Sometimes the elution order is reversed between chiral stationary phases based on these proteins; on the HSA-based phases (*S*)-warfarin elutes before (*R*)-warfarin, whereas on the BSA-based phases the opposite elution order is observed.

A variety of weakly acidic and neutral compounds are resolved on chiral stationary phases based on BSA and HSA. 2-Arylpropionic acid derivatives such as naproxen, flurbiprofen, ibuprofen, ketoprofen and fenoprofen, reduced folates such as leucovorin and 5-methyltetrahydrofolate, and benzodiazepines such as oxazepam, lorazepam and temazepam are separated. **Figure 4** shows enantioseparations of leucovorin, lorazepam hemisuccinate and *N*-benzoyl-phenylalanine on an HSA-based column. However, cationic compounds are not resolved on BSA and HSA phases. The structure-binding relationship for benzodiazepines using HSA stationary phases reveals that the binding of benzodiazepines occurs at a site that contains both a hydrophobic pocket and an area

of cationic charge, and that the chiral recognition occurs in this binding site.

Enantioselectivity of stationary phases based on BSA produced with isolated protein fragments has been investigated. The BSA fragment following peptic digest of BSA has molecular weights of about 35 kDa which is an N-terminal half of amino acid residues 1–307. The BSA fragment phases give longer retentions for benzoin and benzodiazepines, and higher enantioselectivity for lorazepam, benzoin and fenoprofen because of a higher density of chiral recognition site(s), compared with native BSA phases. Figure 5 shows chromatograms of lorazepam enantiomers on BSA and BSA fragment-based columns. However, it is plausible that the conformation of the BSA fragment might be different from that of the native BSA.

Enzyme-based Stationary Phase

Trypsin and α -chymotrypsin are a family of serine proteases. Trypsin-based stationary phases can resolve O-, N,O-derivatized amino acids which are substrates of the enzyme. This means that chiral separations are due to the activity of the enzyme, and that the chiral recognition site is on the enzyme activity site. α -Chymotrypsin stationary phases can resolve amino acids and amino acid derivatives.

When the eluent of pH 7 is continuously delivered, the pepsin-based stationary phases lose their chiral recognition properties. This result reveals that the immobilized pepsin is irreversibly denatured above pH 7. Thus, the use of an eluent with pH less than 6 is

homochlorcyclizine, verapamil, alprenolol and oxazepam on a pepsin-based column. Also, lysozyme-based stationary phases showed chiral recognition ability to cationic and neutral solutes but no resolution of anionic solutes.

α_1 -Acid Glycoprotein-based Stationary Phase

AGP is the major plasma protein responsible for the protein binding of basic drugs. A variety of cationic, anionic and uncharged compounds can be resolved using this stationary phase. Cationic compounds resolved include β -blockers such as alprenolol, oxprenolol, propranolol, metoprolol and pindolol and histamine antagonists such as chlorpheniramine and dimethindene. **Figure 7** shows enantioseparations of metoprolol and pindolol on an AGP-based column. Anionic compounds resolved include 2-arylpropionic acid derivatives such as fenoprofen, ibuprofen and naproxen. As described above, separation of enantiomers is optimized by changing eluent pH, and the type and content of the uncharged organic modifier. However, cationic modifiers such as *N,N*-dimethyloctylamine and tetrabutylammonium bromide and anionic modifiers such as octanoic acid and butyric acid can be used effectively with AGP-based materials. An ion-pairing modifier, *N,N*-dimethyloctylamine, in the eluent gives a large increase in enantioselectivity of racemic acid, naproxen, on an AGP-

based stationary phase, where the retention factor of the second-eluted enantiomer is increased drastically. This is due to an allosteric interaction in which the affinity of the protein for the enantiomer is increased by the addition of the modifier.

AGP consists of a protein domain and sugar moieties, both of which have chiral components. It was thought that drug binding to AGP occurred at a single hydrophobic pocket or cleft within the protein domain of the molecule. However, the role of sugar moieties on enantioselective binding by AGP has not been investigated. It has been reported that sialic acid residues influence the enantioselective binding of basic drugs in different ways. They are not involved in the enantioselective verapamil-AGP binding. On the other hand, they participate in the binding of (*S*)-propranolol but not of (*R*)-propranolol. Further studies are required to clarify the role of sugar moieties in chiral recognition and the chiral recognition mechanism of AGP.

Cellobiohydrolase-based Stationary Phases

Chiral stationary phases based on CBH I can resolve acidic and basic racemates into their enantiomers. Higher enantioselectivity is especially obtained for the separation of β -blocking agents such as propranolol, oxprenolol and metoprolol. **Figure 8** shows a chromatogram of propranolol enantiomers on a CBH I-based column.

CBH I has a structural organization with a terminal, 36 residue-long binding domain connected to the rest of the enzyme (i.e. the core) through a flexible arm. The interconnecting region is rich in serine, threonine and proline residues and is highly glycosylated. The core is enzymatically active. CBH I is enzymatically degraded into two fragments, core

Figure 8 Chromatogram of propranolol enantiomers on a CBH I-based column. HPLC conditions: column, 5.0 mm i.d. \times 250 mm; eluent, sodium-acetate buffer pH 4.7, I = 0.01, containing 0.5% 2-propanol; flow rate, 0.3 mL min⁻¹; detection, 254 nm. (Reproduced with permission from Erlandsson P, Marle I, Hansson L *et al.* (1990) Immobilized cellulase (CBH I) as a chiral stationary phase for direct resolution of enantiomers. *Journal of the American Chemical Society* 112: 4573.)

and binding domain. Each fragment has been shown to contain at least one enantioselective site for propranolol. The dominating enantioselective site for propranolol and other solutes is located on the core, the main part of the enzyme. The three-dimensional structure of the active site of CBH I has been elucidated by X-ray crystallography, and it has been shown that the binding site is a tunnel with the dimensions $0.4 \times 0.7 \times 4$ nm. There are seven acidic amino acid residues, four tryptophan residues and also, tyrosine, serine, threonine, arginine and histidine lining the tunnel. This gives the prerequisite for obtaining stereoselective binding of a broad range of chiral solutes.

Ovogloboprotein-based Stationary Phases

Chiral stationary phases based on chicken ovomucoid (OMCHI) from egg whites have been prepared, which show chiral recognition abilities for a wide range of cationic, anionic and uncharged compounds, similar to AGP phases. However, the chiral recognition ability of OMCHI comes from other glycoproteins, as described below.

Ovomucoid from turkey egg whites (OMTKY) and OMCHI, which exist as three tandem, independent domains, have been isolated, purified and characterized, and columns based on OMTKY and OMCHI domains have been made to test their chiral recognition properties. The third domain of OMTKY and OMCHI consists of glycosylated (OMTKY3S and OMCHI3S) and unglycosylated domains (OMTKY3 and OMCHI3). The OMTKY3 and OMTKY3S, and OMCHI3 and OMCHI3S are enantioselective to at least two classes of compounds, benzodiazepines and 2-arylpropionic acid derivatives. Glycosylation of the third domain does not affect chiral recognition. The chiral recognition mechanism of the OMTKY3 has been elucidated using nuclear magnetic resonance measurements, molecular modelling and computational chemistry. The selected binding model for each of the (*R*)- and (*S*)-enantiomers of U-80 413 (whose structure is illustrated in Figure 9), a 2-arylpropionic acid derivative, with OMTKY3 shows similarities and differences in orientation and intermolecular interactions between the (*R*)- and (*S*)-enantiomers. The carboxyl groups of each enantiomer engage in electrostatic interactions with the positive charge on arginine-21. The carbonyl group on U-80 413's central ring shares a hydrogen bond with the NH_3^+ group of lysine-34. The distinguishing difference between the enantiomers is the proximity of the phenyl group of the (*R*)-enantiomer and phenylalanine-53. However, neither the first nor the second domain of the OMTKY and a

Figure 9 Structure of U-80 413.

combination of the first and second domains, or the second domain of the OMCHI gives chiral recognition ability.

These results suggest that three domains may be needed to work in concert for chiral recognition of various solutes, because columns made with the whole, intact OMTKY and OMCHI can resolve a wide range of weakly acidic, weakly basic and neutral racemates. Recently, a new protein from chicken egg whites has been isolated and characterized. It is termed ovogloboprotein (OGCHI, which means ovogloboprotein from chicken egg whites). It is found that 10% of OGCHI is included in crude OMCHI preparations. OMCHI and OGCHI columns made from isolated pure proteins have been compared with regard to their chiral recognition abilities. It is found that the pure OMCHI gives no chiral recognition abilities, and that the pure OGCHI gives better chiral recognition than those of the impure OMCHI reported previously, as shown in Table 4.

Table 4 Comparison of retention factor (k_1), enantioselectivity (α) and resolution (R_s) of various solutes on columns made with crude OMCHI and isolated OGCHI

Compound	Column					
	Crude OMCHI			OGCHI		
	k_1	α	R_s	k_1	α	R_s
Benzoin	2.50	2.71	6.06	11.4	3.18	10.1
Hexobarbital	0.35	1.00		1.52	1.29	0.83
Alprenolol	2.53	1.12	0.31	15.9	1.13	0.84
Propranolol	7.49	1.12	0.44	42.6	1.18	0.78
Chlorpheniramine	1.03	2.05	3.00	5.42	2.27	5.89
Ibuprofen	4.05	1.18	0.88	9.03	1.39	2.58
Ketoprofen	7.69	1.11	0.82	23.5	1.20	1.97

All values were averages of three replicates. HPLC conditions: column, 2.0 mm i.d. \times 100 mm; eluent, 20 mmol L^{-1} phosphate buffer (pH 5.1)-ethanol 90 : 10 (v/v); column temperature, 25°C; flow rate, 0.2 mL min^{-1} ; detection, 220 nm. (Reproduced with permission from Haginaka J, Seyama C and Kanasugi N (1995) The absence of chiral recognition ability in ovomucoid: ovogloboprotein-bonded HPLC stationary phases for chiral recognition. *Analytical Chemistry* 67: 2539.)

Figure 10 Enantioseparations of (A) ibuprofen, (B) ketoprofen and (C) flurbiprofen on an avidin-based column. HPLC conditions: column, 4.6 mm i.d. \times 150 mm; eluent, 20 mmol L⁻¹ potassium phosphate (pH 6.5) containing 6% ethanol; flow rate, 1.2 mL min⁻¹. (Reproduced with permission from Miwa T, Miyakawa T and Miyake Y (1988) Characteristics of an avidin-conjugated column in direct liquid chromatographic resolution of racemic compounds. *Journal of Chromatography* 457: 227.)

Though only 10% OGCHI was included in the impure OMCHI, the impure OMCHI-based column gave moderate chiral recognition (Table 4). This is due to the fact that OGCHI is preferentially bound to DSC-activated aminopropyl-silica gels compared with OMCHI, despite similarity in their average molecular masses (30 and 27 kDa, respectively).

Other Protein-based Stationary Phases

A number of further minor protein-based stationary phases for HPLC, based on avidin, ovotransferrin and flavoprotein, have been described. Avidin, a basic protein, strongly binds biotin with an association constant of 10^{15} mol L⁻¹. Avidin-based stationary phase shows excellent chiral recognition ability for 2-arylpropionic acid derivatives such as ibuprofen, ketoprofen, flurbiprofen, pranoprofen and fenoprofen. Figure 10 shows enantioseparations of ibuprofen, ketoprofen and flurbiprofen on an avidin-based column. A biotin-bound avidin stationary phase does not exhibit chiral recognition ability, because the biotin modifies the structure of the avidin.

Ovotransferrin is labile to heat and acid, but it seems that it is stable to heat when combined with metal ions such as iron, copper, manganese and zinc. Ovotransferrin is further stabilized by conjugation to silica gel as a chiral stationary phase, and ovo-transferrin-based stationary phases have been used for the separation of a basic compound, azelastine.

Flavoprotein, the riboflavin-binding protein, in egg whites and yolks has been introduced as a chiral stationary phase for HPLC. Egg white and yolk flavoproteins appear to be the product of the same gene but to have undergone different post-translational modifications. The amino acid sequence is the same but the yolk flavoprotein is between 11 and 13

amino acids shorter. There are differences in the carbohydrate links between flavoproteins from egg yolks and whites. Chiral stationary phases based on flavoproteins from egg whites and yolks exhibit chiral recognition abilities for uncharged, anionic and cationic compounds. There is no evidence whether the drugs interact with the riboflavin-binding site or not.

Future Trends

Chiral recognition sites of protein-based stationary phases will be located and their chiral recognition mechanisms will be elucidated using X-ray crystallography, ¹H-nuclear magnetic resonance spectroscopy and computational chemistry. Based on these findings, a protein, protein fragment or protein domain having chiral recognition abilities or a point-mutated protein can be overexpressed by genetic technologies. In the future, we could make protein-based stationary phases, which have better chiral recognition abilities and higher loadability, and are more stable than those so far prepared.

Introduction

Great emphasis is currently placed on differences in biological activities, potencies and toxicities of enantiomeric pharmaceutical compounds. The US Food and Drug Administration (FDA) has recently implemented regulations for the enantiomeric purity of enantiomeric drugs and chemicals. This has led to the development of chromatographic methods for the enantiomeric resolution of racemates including gas chromatography, liquid chromatography, and more recently supercritical fluid chromatography (SFC).

The physicochemical properties of enantiomers are the same except when they are placed in an asymmetric environment. This can be obtained before the chromatographic column or within the column by using a chiral derivatizing agent in the mobile phase or by using a chiral stationary phase.

Formation of Diastereomers by Using a Pre-Column Derivatization

In this method, the racemate is reacted with an optically pure compound leading to formation of diastereomers. Owing to their different physicochemical properties, diastereomers can be resolved by using classical achiral mobile and stationary phases. This method can only be applied to molecules bearing reactive functions such as amines, acids and alcohols. For preparative purposes, partial racemization can occur when recovering the initial enantiomer. This

problem represents the major limitation of this method. Moreover, this method has some disadvantages: (1) the chiral reagent must be optically pure, or its optical purity has to be well known (otherwise, poor accuracy will be achieved); (2) the derivatizing reaction must be quick and quantitative; and (3) the chromatographic behaviour of the derived diastereomers should be suitable (easy separation, good stability under the chromatographic conditions, ease of recovery with absence of racemization during the step leading to the initial enantiomers).

This was the method of choice before the development of chiral stationary phases (CSPs). It is still applied, but usually in order to improve detection limits. The method is not commonly used with SFC although (*S*)-trolox methyl ether has been used to derivatize chiral alcohols for attempted separation by GC and SFC with achiral systems. Using this derivatizing method, several compounds were successfully resolved by SFC but GC failed because of thermal decomposition of the ester derivatives.

Formation of Labile Diastereomers in the Mobile Phase

This method generally consumes chiral reagent. Moreover, the major limitation concerns detection, which must be compatible with the nature of the chiral reagent contained in the mobile phase. In the case of preparative applications the limitation is related to the recovery of the sample, which must be separated from the chiral reagent. Although, the optical purity of the reagent has no effect on the accuracy of the results, it decreases the selectivity of the method. One example of the use of SFC in this way is the chiral separation of amino alcohols using chiral ion pairing (**Figure 1**). In this case SFC analysis time was significantly less than that for high performance liquid chromatography (HPLC) separation.

Figure 1 Chiral separation of propranolol (A) and DPI 101-106 (B) using ion pair SFC. Operating conditions: 100×4.6 mm i.d. column packed with $5 \mu\text{m}$ cyanopropyl-grafted silica (Brownlee GS-GU); mobile phase: carbon dioxide/acetonitrile (80 : 20, v/v) containing $5 \times 10^{-3} \text{ mol L}^{-1}$ of triethylamine and $3.5 \times 10^{-2} \text{ mol L}^{-1}$ of *N*-benzoxycarbonylglycyl-1-proline; pressure 250 bar; temperature: 21°C . (Reproduced from Steuer W, Schindler M, Schill G and Erni F (1988) *Supercritical fluid chromatography with ion-pairing modifiers. Separation of enantiomeric 1,2-aminoalcohols as diastereomeric ion pairs. Journal of Chromatography* 447: 287-296, with permission from Elsevier Science.)

Use of Chiral Stationary Phases

As in HPLC, SFC with chiral stationary phases, which was described for the first time by Mourier and colleagues, is the most powerful technique for the separation of enantiomers.

Capillary Columns

The coupling of SFC-CSPs can be performed either with capillary or packed columns. However, few applications have been described using capillary columns since the number of commercially available GC-CSPs is low and setting up the back-pressure regu-

lator is somewhat difficult to adjust precisely with a capillary column. Packed columns provide greater scope for applications, mainly due to the greater number of chiral stationary phases commercially available and their ease of use. Consequently only SFC on chiral packed columns will be described here.

Packed Columns

CSPs designed for HPLC are widely used in SFC. This is because separations are performed at room temperature so that there is greater interaction energy between CSP-racemate (and therefore higher selectivities) with fewer racemization problems. Packed-column SFC has the same advantages and this is why, since 1985, this technique has been successfully applied to chiral separations. However, the lack of commercial equipment for packed-column SFC has long been a major problem in the development of the technique; this handicap is now being overcome. The advantages of SFC over HPLC include: faster analysis, faster column equilibration, faster method development and also reduced generation of hazardous waste. It must also be underlined that SFC sometime exhibits thermodynamic advantages over HPLC by providing greater selectivity values (particularly with natural polymer CSPs).

Chiral Stationary Phases

The first commercial LC-CSP was described in 1981 and more than 100 CSPs are now commercially available (Table 1). These CSPs can be divided into four groups, depending on their chemical structure and the chiral recognition mechanisms involved.

Group I Group I CSPs are divided into two subgroups. Brush-type CSPs (Pirkle-type and analogues, constitute the first subgroup (IA in Table 1). They are the most amenable to scientific investigation because they work as independent CSPs, since each chiral graft operates independently in distinguishing the solute enantiomers.

Ligand-exchange CSPs (subgroup IB in Table 1) cannot be used in SFC because the formation of the ternary complex, chiral selector- Cu^{II} -solute, takes place almost exclusively in an aqueous medium.

Group II This group contains cyclodextrin CSPs and crown ether CSPs. Only the cyclodextrins have been applied in SFC (Table 1).

Group III The chiral selector is here a polymer, natural (as with amylose and cellulose) or synthetic (as with polyacrylamide) bearing a lot of stereogenic centres and asymmetric cavities. The formation of the

solute-CSP complex involves inclusion of the solute in the chiral cavities acting cooperatively. Group III CSPs (Table 1) can be applied in SFC.

Group IV Group IV contains protein and antibiotic-grafted silica. As for the phases in sub-group Ib, these CSPs cannot be used in SFC.

Applications

The most interesting applications of SFC concern the type IA and III CSPs, and to a lesser extent type II CSPs.

Group IA

As a general rule, most applications concern the brush-type CSPs having a π -electron acceptor charac-

ter. This is because many compounds of pharmaceutical interest contain a π -donor group.

CSPs derived from *N*-(3,5-dinitrobenzoyl)amino acids are among the most widely used for enantiomeric separations of numerous compounds. The early commercialization of the well-known (*R*)-*N*-(3,5-dinitrobenzoyl)phenylglycine-derived CSP ((*R*)-DNBPG), designed by Pirkle and co-workers in 1980, and the easy and inexpensive preparation of this type of CSP, has prompted many researchers to design new π -acid CSPs. Although the scope of applications of these CSPs does not vary very much, all workers agree that small structural changes in the phases can have significant effects on the chromatographic behaviour. Our laboratories have been involved in the development of CSPs derived from tyrosine. Among them, a 'broad-spectrum' CSP has been marketed under the

registered name ChyRoSine-A and an improved version of this has been described. Their enantiomer-recognition abilities have been evaluated both by LC and SFC and the scope of applications including numerous racemates such as benzodiazepines, sulfoxides, phosphine oxides, lactams and β -blockers demonstrated.

An anthrylamine derivative adsorbed onto porous graphitic carbon has been used to separate two commercial anti-inflammatory agents (ibuprofen and flurbiprofen) and a series of racemic tropic acid derivatives. The enantioselective properties of this material were compared with the corresponding silica-based CSP and it was concluded that the former was more efficient.

π -Basic CSPs, deriving from tyrosine and bearing two stereogenic centres, were designed and successfully applied to the enantioseparation of pharmaceutical compounds using SFC. Warfarin and ICI 176334 (a potential nonsteroidal antiandrogen used in the treatment of prostate cancer) were baseline-resolved on these phases without any prior derivatization step into 3,5-dinitrobenzoyl derivatives. Several π -donor CSPs, with (*R*)-*N*-pivaloylnaphthylethylamide as the chiral selector group, have been applied to SFC.

Valine-diamide phases have been used in SFC for the enantioseparation of racemic *N*-4-nitrobenzoylamino acid isopropyl esters. The enantioselectivity in SFC was comparable to that in LC using the mixture 2-propanol/*n*-hexane as mobile phase but the time required for analysis was less than 5 min by SFC.

As a general rule, the use of SFC does not improve enantioselectivity for type I CSPs. The selectivities obtained in LC and SFC are identical, showing that the chiral recognition mechanisms are the same for hexane and carbon dioxide. In this case, the advantage of SFC over LC is of a kinetic nature, giving higher efficiency per unit time and therefore faster analysis. **Figure 2** illustrates the kinetic advantage of SFC over LC by showing the separation of the enantiomers of Oxazepam on ChyRoSine-A in both LC and SFC. At constant resolution, the analysis time by SFC is 6 min, and 24 min by LC. However, it must be emphasized that in some cases different selectivities between LC and SFC are encountered.

The first of these cases concerns the nonconventional separation of π -acceptor solutes on π -acceptor CSPs. In such a case, π - π charge transfer interactions cannot take place during the chiral

Figure 2 LC (A) and SFC (B) separations of the enantiomers of oxazepam using a ChyRoSine-A CSP: a comparison of analysis time at constant resolution ($R_s = 3.5$). Operating conditions: 150×4.6 mm i.d. column packed with $5 \mu\text{m}$ ChyRoSine-A CSP. LC: mobile phase, hexane/ethanol (90 : 10); flow rate, 2 mL min^{-1} . SubSFC: mobile phase, carbon dioxide/ethanol (92 : 8); flow rate, 4.5 mL min^{-1} at 0°C ; outlet pressure 200 bar. Temperature, 25°C ; UV detection at 229 nm. (Reproduced from Bargmann-Leyder N, Tambuté A and Caude M (1992) Chiralité et chromatographie en phase supercritique. A review. *Analysis* 20: 189–200.)

Figure 3 Influence of the nature of the mobile phase on the resolution of *N*-(3,5-dinitrobenzoyl)phenylglycinol on (R)-DNBPG. LC conditions: mobile phase, hexane/ethanol (85:15, v/v) ($k'(r) = 3.9$, $k'(s) = 5.6$) or hexane/chloroform (10:90, v/v) ($k'(r) = 4.3$, $k'(s) = 16.3$); flow rate 2 mL min^{-1} ; temperature, 25°C ; UV detection at 254 nm. SubSFC conditions: mobile phase, carbon dioxide/ethanol (93:7, w/w); flow rate 4.5 mL min^{-1} at 0°C ; average column pressure, 200 bar; temperature, 25°C ; UV detection at 254 nm. (Reproduced from Maccaudière P, Lienne M, Caude M, Rosset R and Tambuté A (1989) Resolution of π -acid racemates on π -acid chiral stationary phases in normal-phase liquid and subcritical fluid chromatographic modes. A unique reversal of elution order on changing the nature of the achiral modifier. *Journal of Chromatography* 467:357–372, with permission from Elsevier Science.)

recognition mechanism. This is why the main mechanism may vary depending on the mobile phase composition, sometimes resulting in a reversal of the elution order. As shown in **Figure 3**, important discrepancies in the selectivity values are noted between hexane/ethanol in LC and the supercritical mobile phase carbon dioxide/ethanol. The chromatographic behaviour observed in SFC is somewhat similar to that observed in LC with hexane/methylene chloride/chloroform mobile phases.

The second major exception concerns the separation of β -blockers using ChyRoSine-A as CSP. Surprisingly, the direct separation of a series of β -

blockers was achieved on commercially available ChyRoSine-A CSP and on its improved version, whereas these solutes appear to be unresolved or poorly resolved by normal-phase liquid chromatography (**Figure 4**; **Table 2**). The chromatographic behaviour (both in SFC and LC) of various propranolol analogues has been thoroughly studied and further spectroscopic investigations carried out. Starting from these data, detailed chiral recognition mechanisms have been proposed, based on molecular modelling. The solute conformations are selected by taking into account the information provided by the ^1H NMR spectra and it appears that the solvating

Figure 4 Comparative chromatograms of the resolution of propranolol on ChyRoSine-A CSP by LC (A) and SFC (B). Operating conditions: 150×4.6 mm i.d. column packed with $5 \mu\text{m}$ ChyRoSine-A CSP. LC: mobile phase/hexane/ethanol containing 1% v/v of *n*-propylamine (95 : 5, v/v); flow rate 1 mL min^{-1} . SFC: mobile phase, carbon dioxide/ethanol containing 1% v/v of *n*-propylamine (90 : 10); flow rate, 4 mL min^{-1} at 0°C , outlet pressure 200 bar. Room temperature; UV detection at 224 nm. (Reproduced with permission from Siret L, Bargmann N, Tambuté A and Caude M (1992) Direct enantiomeric separation of β -blockers on ChyRoSine-A by supercritical fluid chromatography: supercritical carbon dioxide as transient *in situ* derivatizing agent. *Chirality* 4: 252–262.)

effect of carbon dioxide induces a change in conformation of propranolol (Figure 5). This change occurs in the presence of carbon dioxide but only if the solute bears both an amino proton and an ether function separated by three carbon atoms. Without carbon dioxide, (*R*)- and (*S*)-propranolol conformers have geometrical structures such that the chiral recognition process is poor: the chiral centre of the solute cannot develop stereoselective interactions with the CSP and the interactions involved are the same for both enantiomers (Figure 6). On the other hand, the conformation of propranolol in the presence of carbon dioxide is geometrically favourable to the chiral discrimination. The conformations of the chiral stationary phase, (*R*)-solute, (*S*)-solute and their respective associations are shown in Figure 7. In this case, the (*R*)-propranolol conformer involves higher energy interactions with (*S*)-CSP than the (*S*) conformer.

High speed chiral separations (analysis duration < 1.5 min) of β -blockers have been achieved using

a short packed column and a high mobile phase flow rate. The use of high speed chiral separations allows a decrease in solvent consumption (CO_2 and polar modifier), and by minimizing band broadening in the column gives better detectability. As an example, Figure 8 shows the enantioseparation of propranolol and pindolol. These results again demonstrate the kinetic superiority of the SFC over LC. Moreover, in the case of β -blockers, the better kinetics of SFC is combined with enhanced thermodynamics owing to the favoured chiral recognition provided by the conformation of the molecules in the presence of carbon dioxide.

Finally, it should be noted that type I CSPs have been successfully applied to preparative SFC.

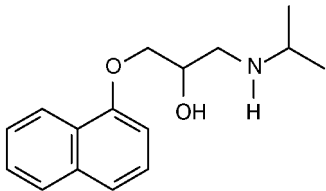

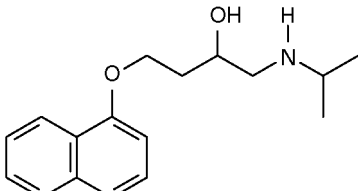

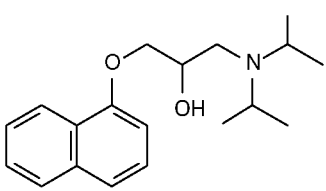

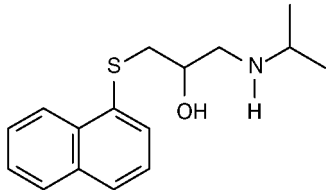

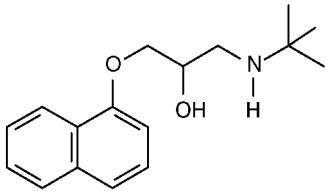

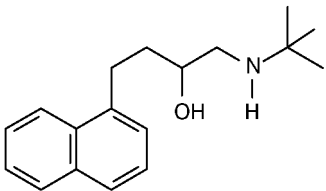

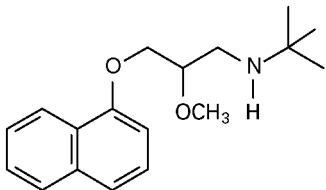

Group II

The scope of applications of a given cyclodextrin is determined by the goodness of the fit between the chiral cavity and the size of the solute to be resolved. If the cavity is too large compared with the solute, there is no preferred orientation (and therefore no selectivity); on the other hand, if the cavity is too small, there is no solute inclusion. Most separations are therefore achieved using β -cyclodextrin for which the internal diameter of the cavity (0.78 nm) is well suited to naphthyl, biphenyl, benzoyl or cyclohexyl moieties present in numerous molecules of pharmaceutical interest. γ -Cyclodextrin is well adapted to molecules bearing large substituents (such as phenobarbital); α -cyclodextrin is preferentially used for smaller molecules bearing a single aromatic group or a small aliphatic chain.

Cyclodextrin CSPs have been used for SFC, although they are, *a priori*, better adapted to the separation of enantiomers in reversed-phase LC. In fact, in normal-phase liquid chromatography, the hydrophobic solvent, e.g. hexane, chloroform, etc., occupies the cyclodextrin cavity and cannot easily be displaced by solutes. The average behaviour of the column is then somewhat similar to that of a diol column (almost no chiral resolution has been obtained using cyclodextrin phases in normal-phase liquid chromatography). The small size of the carbon dioxide molecule means that it can be displaced more easily than other apolar solvents such as hexane from the cyclodextrin cavities. Moreover, the carbon dioxide molecule exhibits an induced dipole moment, giving it a higher polarity than hexane.

The use of polar modifiers induces a decrease in retention (polar modifier competes with the solute and increases the solubility of the solute). In terms of selectivity, all the polar modifiers that have been used (methanol, ethanol, 1-butanol, 2-butanol,

2-propanol) are almost equivalent. Water should not be used since it decreases selectivity significantly.

As reported by Macaudière and co-workers, the use of cyclodextrin CSPs in SFC allows particular selectivities to be obtained. A comparison between solute behaviour in reversed-phase and in normal-phase liquid chromatography clearly demonstrated that SFC and reversed-phase liquid chromatography are two complementary techniques; this result has widened the range of cyclodextrin phase applications. **Figure 9** shows the comparison of the separation of the 2-naphthyl and *o*-anisyl phosphine oxides on Cyclobond I in normal-phase LC and SFC. No or very weak enantiomeric resolution is achieved using normal-phase LC.

Enantiomeric separation of a variety of drugs and related compounds (ancymidol, coumachlor, ibuprofen, mephénytoin, tropicamide, verapamil, etc.) on an (S)-naphthylethylcarbamoylated- β -cyclodextrin phase using sub- and supercritical fluid chromatography has been accomplished by Williams and co-workers. Compounds previously resolved on native or derivatized cyclodextrin CSPs in LC using reversed-phase or polar organic mobile phases could be resolved in SFC using a simple carbon dioxide/methanol eluent. Resolution of cromakalim was

not obtained on the (*S*)-naphthylethylcarbamoylated- β -cyclodextrin CSP using LC, but was readily accomplished using SFC (Figure 10). The separation of the enantiomers of *N*-(3,5-dinitrobenzoyl)valine methyl ester, ancymidol and proglumide was also obtained in a single run using carbon dioxide/methanol eluent, whereas the same separations in LC required three different mobile phases.

Group III

Chiralcel-OD CSP tris(3,5-dimethylphenyl carbamate cellulose) has been used successfully for the SFC enantioseparation of β -blockers, potassium channel activator analogues and other compounds. A Chiralpak-AD column, tris(3,5-dimethylphenyl carbamate amylose), has been used to resolve enantiomeric mixtures of nonsteroidal anti-inflammatories.

Other CSPs derived from cellulose have been successfully applied to the SFC enantioseparation of compounds of pharmaceutical interest. For example, an intermediate in the synthesis of a drug targeted for cardiac arrhythmia was separated on Chiralcel-OB; the four optical isomers of a new calcium channel blocker, LF 2.0254, were resolved on Chiralcel-OJ; and some CSPs have been applied to the SFC separation of various frequently used drug racemates such as profens and barbiturate derivatives, benzodiazepines, etc.

A Chiralcel-OD-H column and an achiral aminopropyl column have been employed for the analysis of products formed in rat liver microsomal metabolism

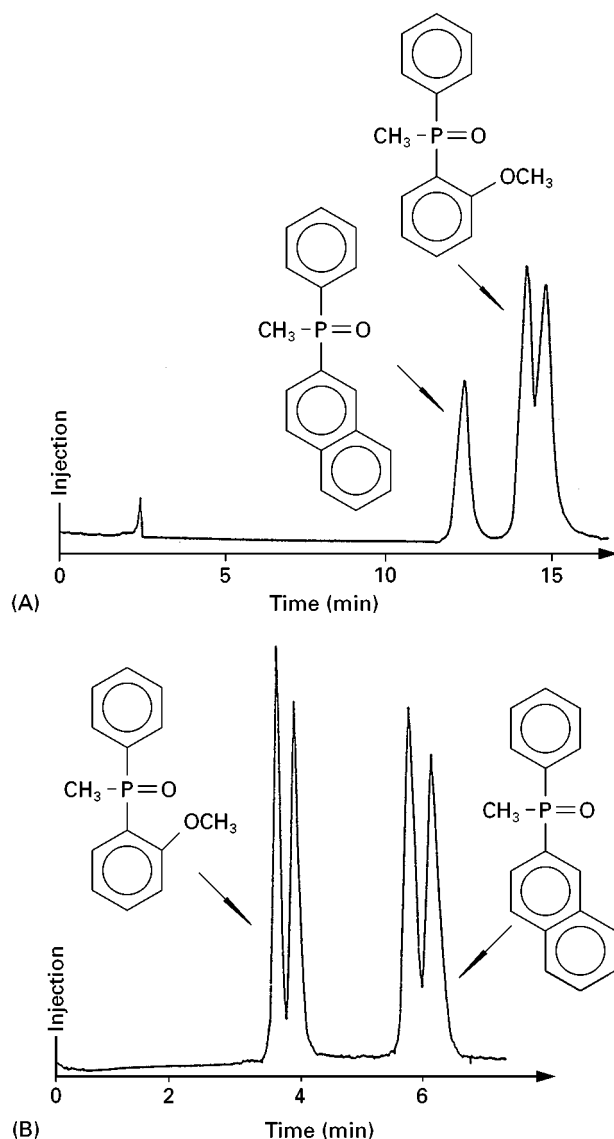

Figure 9 Comparison of the separation of the 2-naphthyl and *o*-anisyl phosphine oxides on Cyclobond I using LC and SFC. LC conditions: mobile phase, hexane/ethanol (85 : 15, v/v); flow rate, 1 mL min⁻¹; UV detection at 234 nm. SFC conditions: mobile phase, carbon dioxide/methanol (94 : 6, w/w); flow rate, 4.5 mL min⁻¹; temperature 25°C; pressure, 150 bar; UV detection at 234 nm. (Reproduced from Williams KL, Sander LC, and Wise SA (1996) Comparison of liquid and supercritical fluid chromatography using naphthylethylcarbamoylated- β -cyclodextrin chiral stationary phases. *Journal of Chromatography A* 746: 91–101, with permission from Elsevier Science.)

characteristics)). This coupling allowed the authors to achieve baseline separations with all solutes investigated, basic (β -blockers, benzodiazepines)

Figure 11 SFC separation of ibuprofen (1), fenoprofen (2), clenbuterol (3), propranolol (4) and lorazepam (5) using the serial coupling of different CSP columns. Operating conditions: columns, Chiralpak AD-Chiralcel OD-Chirex 3022; mobile phase, carbon dioxide/methanol (0.5% triethylamine + 0.5% trifluoroacetic acid) with methanol programmed from 4% (5 min) to 30% at 5% min⁻¹; flow rate 2 mL min⁻¹; temperature, 25°C; pressure, 200 bar. (Reproduced with permission from Kot A, Sandra P and Venema A (1994) Sub- and supercritical fluid chromatography on packed columns a versatile tool for the enantioselective separation of basic and acidic drugs. *Journal of Chromatographic Science* 32: 423–448.)

and acidic (nonsteroidal anti-inflammatory drugs, β -agonists). As an example, **Figure 11** shows the separation of ibuprofen, fenoprofen, clenbuterol, propranolol and lorazepam in a modifier-programmed run.

Systematic comparison of the chiral recognition mechanisms in LC and SFC for type III CSPs has been

performed. It appears that, contrary to what occurs for type I CSPs, important discrepancies in selectivity values may exist between LC and SFC. The systematic comparison of LC and SFC for Chiralcel-OD and Chiralpak-AD CSPs demonstrates clearly that the presence of polar functional groups such as primary or secondary hydroxyl or amine functions may cause

Figure 12 Comparison of LC and SFC for the separation of mefloquine (A), viloxazine (B) and temazepam (C) using Chiralcel OD CSP. Operating conditions: column, Chiralcel OD. LC, mobile phase hexane/ethanol containing 1% (v/v) of *n*-propylamine (90 : 10, v/v) for (A) and (C), 50 : 50 (v/v) for (B); flow rate 1 mL min⁻¹; room temperature. SFC: mobile phase, carbon dioxide/ethanol containing 1% (v/v) of *n*-propylamine 90 : 10 (v/v) for (A) and (B) 95 : 5 (v/v) for (C); flow rate, 2 mL min⁻¹; temperature, 25°C; pressure: 200 bar. UV detection. Separations are optimized for selectivity. (Reproduced with permission from Bargmann-Leyder N, Tambuté A and Caude M (1995) A comparison LC-SFC for cellulose and amylose-derived chiral stationary phases. *Chirality* 7: 311–325.)

large discrepancies in selectivity between LC and SFC. This result is peculiar to cellulose and amylose-derived CSPs, for which the interactions involved in chiral recognition are not always well balanced. Therefore, in the case of chiral resolution of polar solutes, the analyst should try both LC and SFC so that the more stereoselective one can be chosen. Figure 12A–C show some examples of the different selectivities that may exist between LC and SFC for polymer-type CSPs.

Other polymer-type CSPs have been used in SFC, such as those based on polymethacrylates of helical conformation and a polysiloxane CSP (polyWhelk-O), the 'polymeric version' of the commercially available brush-type CSP, Whelk-O 1. For the latter, the comparison was performed between the polymeric CSPs and its brush-type analogue, and it appeared that the polyWhelk-O CSP affords greater enantioselectivity and shorter retention under the same conditions.

Conclusion

Chiral separation is one of the fields where SFC is recognized to have better characteristics than HPLC, both from a kinetic and sometimes thermodynamic point of view.

In general, SFC offers faster separations than LC and often better selectivity values (particularly with cellulosic and amylosic polymer-type chiral stationary phases, and also with brush-type CSPs in particular cases). Consequently, SFC should be considered as a powerful analytical tool for the separation of basic and acidic drugs.

Capillary columns should be chosen for the analysis of chiral compounds having a low or medium polarity. On the other hand, packed columns are preferred for analytes of high polarity for which a polar modifier must be added to the supercritical carbon dioxide mobile phase.

Currently, to meet the requirements of quality control laboratories, most analyses are performed with packed columns. This is mainly due to the progress in

SFC instrumentation (full control over many chromatographic parameters and particularly full control of the pressure). Analysts are looking for the chiral column that is best able to achieve racemate separation easily and in a single run. This objective will probably never be achieved, but we can expect that the serial coupling of chiral columns (two or three) will allow some progress in this direction owing to the kinetic advantage exhibited by SFC over LC.

Synthetic Multiple Interaction ('Pirkle') Stationary Phases

C. J. Welch, Merck & Co. Inc., Rahway, NJ, USA

Copyright © 2000 Academic Press

Introduction

Among the many types of chiral stationary phases (CSPs) that have been developed, synthetic multiple

interaction (Pirkle-type, or brush-type) CSPs have proven to be among the most useful for many liquid chromatographic enantiomer separations. These CSPs consist of an enantioenriched small molecule selector immobilized on an inert chromatographic support, typically silica gel. Separation is achieved when the two enantiomers of the analyte are differentially adsorbed by the CSP (Figure 1). A combination

Figure 1 Enantiomer separation on CSPs is made possible by formation of transient diastereomeric adsorbates with differing free energies. In this illustration, the analyte enantiomers are depicted as right and left hands, and the CSP is depicted as immobilized right-handed gloves.

of simultaneous, geometrically constrained, intermolecular interactions utilizing forces such as hydrogen bonding, π - π attraction, ionic interactions, and steric repulsion can result in diastereomeric adsorbates with differing free energies, the prerequisite for enantioseparation.

Brush-type CSPs are just one of the several types of CSPs that have been developed to date. Other types include CSPs based on natural polymers such as polysaccharides or proteins, artificial polymers, and 'imprinted' polymers. Exactly what constitutes a brush-type CSP is a matter of some debate. In the broadest definition, CSPs based on immobilized cyclodextrins, antibiotics, etc. should perhaps be included in this category. However, this article will deal primarily with the synthetic CSPs developed by Professor William H Pirkle.

Background

Although Pirkle's name is strongly associated with the development of synthetic multiple interaction CSPs, several important materials of this type were developed by earlier researchers. Landmark events from the 1960s include the development of TAPA CSPs and chiral GC stationary phases. The 1970s brought a number of further advances, including Davankov's development of ligand exchange CSPs, Baczuk's pioneering development of a synthetic CSP designed specifically for the chromatographic separation of the enantiomers of a particular analyte molecule (DOPA), and Cram's development of chiral crown ether CSPs. During this same decade, Pirkle's investigations into the development of ^1H NMR chiral solvating agents led to the development of several useful brush-type CSPs.

Advantages of Brush-Type CSPs

In general, brush-type CSPs possess a number of advantages; since the selector is a small molecule, which is often completely synthetic, a structure which contains no labile or reactive components can usually be developed and the mode of attachment of the selector to the chromatographic support can be chosen for durability. Brush-type CSPs are typically covalently attached to the chromatographic support. Thus, most brush-type phases are chemically robust and are generally quite long-lived. Longevity is desirable for an analytical CSP, but truly essential for a preparative CSP, where continuous operation for several years may be required. The chemical robustness of brush-type CSPs results in the ability of these materials to be used with a wide variety of mobile phases, which provides greater flexibility in method development, especially when poorly soluble analytes are being investigated. The ability to utilize a variety of mobile phases is of even greater importance in preparative chromatography, where compound solubility can drastically limit enantioseparation productivity.

An additional advantage of brush-type phases stems from the fact that the selectors which are used are typically small molecules with molecular mass of less than 11000 Da. Consequently, the selectors can be very densely arrayed on the chromatographic surface, resulting in a phase which is highly resistant to sample overload and which has a very high preparative capacity.

Finally, most synthetic CSPs are available in either enantiomeric form. Consequently, either elution order (+ before - , or - before +) can be chosen. Elution of the minor enantiomer before the major is generally preferred in analysis, while elution of the desired component before the undesired can greatly increase productivity in preparative HPLC.

Survey of Some Important Pirkle-Type CSPs

The Beginnings: A Carbinol CSP

The Work on CSPs in the Pirkle laboratories grew out of studies on ^1H NMR chiral solvating agents. Immobilization of an analogue of the enantiopure chiral resolving reagent, trifluoromethyl-9-anthryl carbinol, afforded a CSP capable of separating the enantiomers of electron-deficient aromatic sulfoxides and many other racemates. Further studies showed that 3,5-dinitrobenzamide (DNB) derivatives of the enantiomers of a variety of amines, amino alcohols, amino acids and related compounds were separated with the following CSP structure [I].

Structure [I]

Principle of Reciprocity, and its Importance in CSP Development: Development of DNB Amino Acid CSPs

The observation that the enantiomers of some DNB derivatives are well resolved on CSP structure [I] prompted an investigation of the reciprocal situation. As a general rule, if a CSP is useful for separating the two enantiomers of an analyte, then a second CSP derived from one of the enantiomers of that analyte should be useful for separating the enantiomers of compounds which are structurally related to the chiral selector of the original CSP. This concept is known as the 'principle of reciprocity', and has been of great use in the development of new CSPs by Pirkle and his co-workers. The principle holds true generally, although the manner in which the chiral selector is tethered to the silica surface can influence chiral recognition in either a beneficial or detrimental fashion. After finding that several DNB phenylglycine-derived analytes were particularly well resolved on CSP structure [I], Pirkle and co-workers prepared and evaluated several phases derived from DNB phenylglycine and related compounds. The ready availability of enantiopure (*R*)-phenylglycine, which is utilized in the commercial production of an antibiotic, suggested that phenylglycine-derived CSPs might provide an economical and convenient method for resolving the enantiomers of the highly useful chiral solvating agent, trifluoromethyl-9-anthryl carbinol, and perhaps other alcohols as well.

As expected, CSP structure [II] afforded resolution of the enantiomers of the trifluoromethyl-9-anthryl carbinol chiral solvating reagent as well as some related compounds. The related ionically bonded amino acid-derived CSPs structures [III] and [V] were

Structure [II] (DNB PG)

Structure [III] (DNB PG-Ionic)

Structure [IV] (DNB Leu)

Structure [V] (DNB Leu-Ionic)

subsequently prepared and also found to be useful for the resolution of the enantiomers of a variety of arylalkylcarbinols, with the phenylglycine-derived CSP structure [III] generally performing better than the leucine-derived CSP structure [IV]. CSP structure [III] was found to be widely useful for the separation of the enantiomers of racemates from a variety of functional group classes, and was shown to be useful for the gram-scale preparative resolution of racemates using automated preparative chromatography. The general ability of CSP structure [III] to resolve the enantiomers of a variety of analytes led to its introduction as the Pirkle 1A CSP by Regis Chemical Company in 1980 – the first commercially available HPLC chiral stationary phase. Somewhat later, CSP structures [II], [IV] and [V] were also made commercially available, and today a wide variety of CSPs incorporating the highly useful DNB moiety have been developed. Commercialization of these early Pirkle phases provided researchers in a number of fields with tools for separating the enantiomers of structurally diverse racemates. Surprisingly, the ionically tethered DNB amino acid CSP structures [III] and [V], are quite long lived when used with relatively non-polar mobile phases, although they are readily degraded when highly polar eluents such as methanol or water are used.

CSPs based on DNB derivatives of the amino acid, tyrosine, were subsequently developed by a team of French researchers including Caude, Rosset, and Tambuté, and a CSP based on DNB naphthylglycine was developed by Ôi and co-workers in Japan. The 3,5-dinitrobenzamide group has proven useful in the development of a number of additional phases, as will be described later.

Second Generation Pirkle CSPs with Electron Rich Aromatic Groups

Studies in the Pirkle laboratories and elsewhere showed that the DNB amino acid-derived CSPs were capable of separating the enantiomers of a wide variety of analytes possessing electron-rich aromatic groups. At this point, it was only natural to again turn to the principle of reciprocity and prepare and evaluate 'reciprocal' materials based on some of these structures. A number of reciprocal phases were prepared and evaluated, although they lacked the requisite generality required of a commercial CSP. Nevertheless, these studies revealed many important design features that would prove useful later.

The enantiomers of aryl hydantoin are well resolved on DNB amino acid-derived CSPs, and several hydantoin-based CSPs were prepared to study the mechanisms for chiral recognition of these types of analytes and to probe the ability of this type of phase to afford separation of various racemates.

Separation of the enantiomers of a number of aryl-substituted phthalides was studied using DNB amino acid-derived CSPs such as CSP structures [III] and [V], and a detailed study of the effect of analyte structure on chromatographic performance led to some optimized structures for chiral recognition. One such compound was used to prepare a reciprocal aryl phthalide CSP which, as expected, showed a general ability to resolve a number of racemates containing electron-deficient aromatic systems.

Another class of compounds which are well resolved on the DNB amino acid-derived CSPs are general amide structures bearing at least one aromatic ring. In an extensive series of studies, Pirkle, Hyun and co-workers prepared and evaluated more than 10 CSPs derived from various analogues of (1-naphthyl)ethylamine (α -NEA) in which a variety of different tether geometries and substituent patterns were explored. Study of this group revealed a number of interesting and useful principles of CSP design. However, the CSPs themselves were somewhat limited in that they were useful primarily for separation of the enantiomers of analytes bearing electron-deficient aromatic groups. Similar CSPs were prepared and studied by Ôi and co-workers.

N-Aryl Amino Acid-Derived CSPs

The development of second generation Pirkle phases with electron-rich aromatic groups reached its zenith with the investigations by Pirkle and Pochapsky of compounds derived from the enantiomers of the readily prepared electron-rich *N*-aryl amino acid derivatives. This is perhaps the best understood chiral recognition system yet studied. In some preliminary studies, it was shown that *N*-aryl amino acid derivatives were well resolved using the DNB Leu-Ionic CSP structure [V]. Subsequently, the structural requirements for chiral recognition were defined, and a chiral recognition rationale was proposed. The high degree of enantioselectivity observed in this system ($\alpha > 10$ in some cases) can be attributed to the intimate association of the two components of the more stable diastereomeric adsorbate as illustrated later. This chiral recognition system has been studied at great length using spectroscopic as well as chromatographic techniques. An X-ray structure of a 1:1 complex of soluble analogues of the compounds shows essentially the same adsorbate structure as that initially proposed based upon chromatographic and spectroscopic studies (structure [VI]):

A reciprocal *N*-(2-naphthyl)valine-derived stationary phase was prepared and shown to provide unprecedented levels of resolution for a variety of racemates containing electron-deficient aromatic groups. The related alanine-derived CSP structure [VII] was subsequently reported, and commercialized, and has proven to be a valuable and widely used research tool:

Subsequent structural refinements led to the preparation and commercialization of the leucine-derived CSP structure [VIII], which generally affords significantly greater enantioselectivity in the separation of DNB-containing enantiomers than does CSP structure [VI]. The predominant effect seems to be a greatly diminished retention of the initially eluted enantiomer, presumably owing to the ability of the more

Structure [VI]

Structure [VII] (N_2N -Ala CSP)Structure [VIII] (N_1N -Leu CSP)

bulky leucine sidechain to inhibit approach of the least retained enantiomer from the undesired face of the aromatic ring of the CSP.

These phases have proven to be widely useful for separating the enantiomers of chiral amines, amino alcohols, amino acids, etc., and are sometimes also useful for separating the enantiomers of chiral alcohols, thiols, etc. However, analysis with these phases generally requires that the analyte be derivatized so as to incorporate an electron-deficient aromatic group. Typically, derivatization reagents such as 3,5-dinitrobenzoyl chloride or 3,5-dinitrophenylisocyanate are used. Despite this somewhat bothersome need to make derivatives, these CSPs remain quite useful and show a tremendous generality.

Recently, a group of CSPs based on proline anilides have been developed in the Pirkle laboratories. These exhibit remarkable enantioselectivities for some DNB derivatives.

Improved DNB CSPs

The design of CSPs is an evolutionary process so that continuing refinements and improvements in both the understanding of chiral recognition and the design of such phases are constantly being made. Several CSPs,

representing improvements upon the widely used DNB phenylglycine-derived CSP structure [II] have been developed in the Pirkle laboratories and subsequently commercialized. The first of these, the β GEM 1 CSP (CSP structure [IX]), grew out of studies of the enantiopurity analysis of some chiral β -lactams. The finding that some DNB β -amino acid derivatives were well resolved led to the preparation and evaluation of the DNB β -amino acid-derived structure [IX]. An X-ray crystal structure of the selector used in CSP structure [IX] shows the *t*-butyl and phenyl substituents projecting from opposite faces of the stationary phase. The bulky *t*-butyl substituent at the 2-position is thought to play a major role in controlling the conformation of this phase, preventing intramolecular hydrogen bonding, and restricting access to one face. The β GEM CSP is useful for the separation of the enantiomers of anilide derivatives of aromatic carboxylic acids and *N*-protected amino acids.

As will be related later, the most general CSP yet developed in the Pirkle laboratories, the Whelk-O 1 (CSP structure [X]), was actually designed to separate the enantiomers of one particular compound, naproxen. In addition to resolving the enantiomers of

Structure [IX] (β -GEM I CSP)

Structure [X] (Whelk-O 1 CSP)

naproxen and nearly all related nonsteroidal anti-inflammatory drugs (NSAIDs) this CSP is useful for resolving the enantiomers of analytes from a host of functional group classes.

A very useful DNB-containing CSP based upon diphenylethylenediamine has been prepared and investigated by Uray, Lindner and Maier. This CSP, commercialized as the ULMO CSP (structure [XI]), shows a general ability to separate the enantiomers of a number of analytes containing electron-rich aromatic groups. In addition, it shows an ability to separate the enantiomers of aryl carbinols which is unsurpassed among Pirkle-type CSPs.

Another improved DNB-containing CSP based on the relatively inexpensive *trans* 1,2-diaminocyclohexane (DACH) was developed by the research team of Gasparrini, Misiti, Villani, and co-workers; this phase has never been commercialized, but has been studied extensively.

β -Blocker-Specific CSPs

In the mid-1980s, some of the principles of CSP design were becoming fairly well understood in the Pirkle laboratories, and attempts were made to design selectors for particular target racemates of significant scientific and economic importance.

For example, the enantiomers of the β -blocker drug propranolol had been shown to be marginally resolved on the DNB phenylglycine-derived CSP structure [II] as any of a variety of *N*-acylated derivatives.

A research programme directed at developing a phase capable of separating the enantiomers of underivatized propranolol enantiomers was undertaken. A group of three CSPs were designed, prepared, evaluated, and shown to separate the enantiomers of propranolol with the elution order predicted by the chiral recognition model. Several other β -blockers were similarly resolved, however, the poor chromatographic efficiency of these materials limited their practical utility.

In an effort to overcome this obstacle, a group of amino phosphonic acid-derived CSPs were prepared and shown to provide improved resolution of propranolol. Consequently, CSP structure [XII] was prepared, evaluated, and found to provide very good resolution for the enantiomers of propranolol and a number of related β -blockers. This stationary phase was commercialized as the α -Burke I CSP. Subsequent minor improvements in the tethering chemistry led to an improved version commercialized as the α -Burke II CSP (structure [XII]).

Naproxen-Specific CSPs Using the Immobilized Guest Method

As mentioned earlier, one of the most general Pirkle-type CSPs resulted from a study aimed at developing something which would be useful for separating the enantiomers of the drug, naproxen. At the time of the inception of this project, separation of the enantiomers of naproxen and related NSAIDs with Pirkle-type CSPs generally required formation of derivatives. The finding that underivatized naproxen enantiomers could be marginally resolved on the β -GEM 1 CSP prompted an investigation into the development of improved separations. Drawing on the familiar principle of reciprocity, a new approach termed the 'immobilized guest method' was utilized in this study. Two CSPs were prepared from enantiopure naproxen, and these were used to investigate the enantioseparation of a variety of different chiral analytes. This study led to an understanding of the structural requirements for enantioselective naproxen recognition, and a new chiral selector incorporating

Structure [XI] (ULMO CSP)

Structure [XII] (α -Burke I CSP)

many of these key structural features was proposed. This new selector was synthesized and found to be well separated on the immobilized guest naproxen CSPs. Larger scale synthesis, resolution, and immobilization of the selector afforded a CSP which resolved naproxen enantiomers with a very high degree of enantioselectivity ($\alpha = 2.25$). In addition, structurally related NSAIDs such as ibuprofen, ketoprofen, flurbiprofen, etc. are also resolved. Subsequent mechanism-based structural modifications led to the development and commercialization of the Whelk-O 1 CSP (CSP structure [X]) which affords improved resolution of NSAID enantiomers. In addition to resolving the enantiomers of NSAIDs, the Whelk-O 1 CSP has proven to be the most general CSP developed to date in the Pirkle laboratories, as it is capable of resolving the enantiomers of racemates from a host of functional group classes.

A number of variations on the Whelk-O structure have been developed in the Pirkle laboratories and at Regis Technologies. For example, the same selector immobilized via a trifunctional silane linkage has been commercialized as the Whelk-O II CSP (structure [XIV]). This CSP is more resistant to selector cleavage under harsh mobile phase conditions.

Another analogue of the Whelk-O CSP has proven useful for separations utilizing supercritical or subcritical carbon dioxide as an eluent. This phase, commercialized as the PolyWhelk-O CSP, is prepared by first immobilizing the Whelk-O chiral selector onto a polysiloxane polymer, then covalently bonding the resulting polymer to silica gel. The resulting material often shows improved efficiency and enantioselectivity when operated in the SFC mode.

New Trends in Design and Development of Pirkle-Type CSPs

The design and development of new CSPs continues at an active pace in the Pirkle laboratories, with an emphasis on using an array of analytical tools to develop a mechanistic understanding of CSP behaviour. Developing CSPs which will be useful in the preparative chromatographic separation of pharmaceutical enantiomers is another major research area.

A new method for microscale synthesis and evaluation of libraries of Pirkle-type phases has recently

been developed at Regis Technologies. In this technique, libraries of CSPs are prepared on a 50 milligram scale by solid phase synthesis on silica particles. The resulting libraries are then rapidly evaluated using a process which does not require packing into a column. This technique provides a useful tool for rapidly determining which CSP from a library of many hundreds shows the greatest enantioselectivity for a particular analyte. In addition, some of the necessary structural requirements for chiral recognition can be determined by comparing the relative performance of various CSPs in the library. This information can, in turn, suggest further CSP libraries, which can be prepared and evaluated. Ultimately, the process can lead to discovering CSPs which display preparatively useful enantioselectivity for given target racemates.

Structure [XIII] (α -Burke II CSP)

Structure [XIV] (Whelk-O II CSP)

Structure [XV]

Figure 2 Relative enantioselectivity seen by a library of 50 dipeptide DNB CSPs for the enantiomers of a test racemate.

For example, preparation of a library of 50 dipeptide DNB CSPs and screening for the ability to separate the enantiomers of the test analyte shown (structure [XV]) afforded the results presented in Figure 2, which suggest that bulky groups in the aa 2 position and hydrogen bonding groups in the aa 1 position are advantageous.

Subsequent preparation and evaluation of such a 'focused' library revealed a number of new CSPs with very high enantioselectivity for the target analyte. One of the better performing members of this library was prepared on a larger scale, packed into a column, and shown to be able to afford exceptionally high productivity for the preparative separation of the enantiomers of the racemic test analyte. This new approach to CSP development promises to be very useful for large-scale preparative chromatographic enantioseparation, and a variety of structurally diverse CSP libraries are now being investigated by a number of different research groups.

Conclusion

A number of Pirkle-type CSPs are of great use in the chromatographic separation of enantiomers. Several of these materials are commercially available and widely used in diverse research disciplines. An ever-increasing understanding of the requirements for chiral recognition and the design of useful CSPs is evident from a survey of Pirkle's work over the past two decades. The entry of other research groups into the area of CSP design suggests that there will be continued developments in this area in coming years.

Introduction

In chiral chromatography, two diastereomeric adducts with different physicochemical properties are formed during elution. The adducts differ in their stability (in chiral stationary phases, CSPs, or chiral coated phases, CCPs) and/or in their interphase distribution ratio (in chiral mobile phases, CMPs).

According to Dalglish, three active positions of the selector must interact simultaneously with the active positions of the enantiomer to reveal differences between optical antipodes. This is a sufficient condition for resolution to occur but it is not essential. Chiral discrimination may happen as a result of hydrogen bonding and steric interactions, making only one attractive force necessary in this type of chromatography. Moreover, the creation of specific chiral cavities in a polymer network (as in 'molecular imprinting' techniques) could make it possible to base enantiomeric separations entirely on steric fit.

Chiral Stationary Phases and Chiral Coated Phases

Few chiral phases are used in TLC; one of the main reasons for this is that chiral stationary phases with very high UV background can only be used only with fluorescent or coloured solutes. For example, amino-modified ready-to-use layers bonded or coated with Pirkle-type selectors, such as *N*-(3,5-dinitrobenzoyl)-L-leucine or *R*(-)- α -phenylglycine, are pale yellow and strongly adsorb UV light. Another reason is the high price of most CSPs.

The most widely used CSPs or CCPs are polysaccharides and their derivatives and silanized silica gel impregnated with an optically active copper (II) complex of derivatized hydroxyproline. The use of silica gel impregnated with chiral polar selectors, such as D-galacturonic acid, (+)-tartaric acid, (-)-brucine, L-aspartic acid or a complex of copper (II) with L-proline, should also be mentioned.

In CSPs, owing to the nature of the polymeric structure, the simultaneous participation of several chiral sites or several polymeric chains is conceivable. In CCPs, the chiral sites are distributed at the surface or in the network of the achiral matrix relatively far

away from each other and only a bimolecular interaction is generally possible with the optical antipodes to be separated.

Cellulose

The linear polysaccharide cellulose is composed of (+)-D-glucose units and its relative molecular mass ranges from 2.5×10^5 to 1×10^6 or more. The long chains are arranged on a partially crystalline fibre structure and held together by numerous hydrogen bonds between the hydroxyl groups. The hydrolysis of cellulose with 2.5 mol L^{-1} hydrochloric acid at *c.* 100°C removes amorphous material and yields a more crystalline polymer called 'microcrystalline cellulose' and marketed as Avicel by several companies.

The mechanism of chiral recognition is not yet completely clarified even though a significant role is attributed to the cellulose structure and to the hydroxyl groups, the protection of which with BrCN resulted in the loss of chiral recognition. The optical antipodes resolved are highly polar, such as amino acids, with multiple sites for hydrogen bond formation.

Cellulose Derivatives

Among derivatized polysaccharides, cellulose triacetate (CTA) is the most used stationary phase for the resolution of racemic compounds by TLC.

The different fit of the two enantiomers into the laminae of the polymer leads to separation of the optical antipodes which is mainly governed by the shape of the solutes (flat molecules showing a better permeation into the cavities) and only to a minor extent by electrostatic interactions involving the functional groups of the molecules. Hence the name 'inclusion chromatography'. In addition, the chiral recognition of CTA depends strongly on its structure and the type of eluent and increases as the crystallinity of the polysaccharide is increased. Microcrystalline cellulose triacetate (MCTA) can be prepared from microcrystalline cellulose with almost complete preservation of microcrystallinity. Usually, the type of eluent and its composition are important for chiral recognition because these produce different swelling of MCTA, which in turns enables the separation of solutes of different sizes and characteristics.

The use of *n*-hexane-isopropanol mixtures resulted in unsatisfactory separations since extremely elongated spots are generally obtained. Aqueous-alcoholic solutions have the opposite effect, giving rise to round and compact spots.

This CSP is able to resolve a broad range of structurally different racemates. In general, more polar molecules require a higher percentage of water than hydrophobic compounds.

Hydrophobic Silica Gel Impregnated with Copper (II) Complex of (2*S*,4*R*,2'*RS*)-*N*-(2'-hydroxydodecyl)-4-hydroxyproline

The structure of the selector is shown in Figure 1. Chiralplate and HPTLC-CHIR are the only precoated plates built up from such material. The chiral layer on the latter plates is combined with a so-called 'concentrating zone'. The sample to be separated is applied to this small band and is transported with the solvent front, forming a narrow band at the interface of the two sections; consequently, a higher efficiency of the separation process is obtained.

Many racemates have been resolved on both layers by ligand-exchange chromatography (LEC). The separated enantiomers are those capable of forming diastereomeric complexes of different stability with the metal ion and the chiral selector. The requirement of sufficient stability of the ternary complex involves five-membered ring formation and compounds such as α -amino and α -hydroxy acids are the most suitable.

Chiral Mobile Phases

CMPs permit the use of conventional stationary phases and show fewer detection problems than CSPs or CCPs. However, high cost chiral selectors (i.e. γ -cyclodextrin) are certainly not advisable for TLC.

Enantiomer separations have been achieved using chiral mobile phases in both normal and reversed-phase chromatography. The first technique employs silica gel and, mostly, Diol F₂₅₄ HPTLC plates (Merck) and, as chiral selectors, D-galacturonic acid, *N*-carbobenzoxy(CBZ)-L-amino acids or peptides, 1*R*-(-)-ammonium-10-camphorsulfonate and 2-*O*-[(*R*)-2-hydroxypropyl]- β -cyclodextrin.

Most separations have been obtained by reversed-phase chromatography on hydrophobic silica gel with β -cyclodextrin (β -CD) and its derivatives, bovine

serum albumin (BSA) and the macrocyclic antibiotic vancomycin as chiral agents.

Unmodified and Modified β -Cyclodextrins as Mobile-Phase Additives

Among the three cyclodextrins (α , β , γ), only β -CD and its derivatives have been used for successful resolution of various racemates by TLC. In an aqueous solution β -CD is represented as a truncated cone with different sized mouths (0.60–0.65 nm); the height of the cavity is 0.78 nm. The 2- and 3-hydroxyl groups are oriented towards the outside and are responsible for the aqueous solubility properties of this oligosaccharide. The hydrogen atoms and glycosidic oxygen groups are located inside the molecule, forming the relatively hydrophobic cavity that interacts with organic optical isomers to form diastereomeric inclusion complexes. Under reversed-phase conditions, the combination of hydrophobic and steric interactions with hydrogen bonding between the chiral solutes and the 2- and/or 3-hydroxyl groups may be the cause of enantioselectivity.

Aqueous-organic solutions (i.e. methanol-water or acetonitrile-water mixtures) are usually used as eluents. β -CD is enantioselective in TLC only at the high concentrations reached by adding large amounts of urea, which increases the aqueous solubility of β -CD more than ten-fold. However, urea tends to compete with solutes for the preferred location in the hydrophobic cavity, thus decreasing the separation factor. Chemical modification with hydroxypropyl, hydroxyethyl or methyl groups has been used to increase the solubility of β -CD and its complexes in water, eliminating the need to use urea. Optimization of the enantioselectivity can be achieved by modifying the concentration and nature of organic solvent, pH and buffer concentration of the eluent.

Bovine Serum Albumin as Mobile-Phase Modifier

BSA is a protein of relative molecular mass 66 210, consisting of 581 amino acids in a single chain. It is a relatively acidic protein (isoelectric point 4.7), highly soluble in water, but precipitates from high salt solutions. At pH 7.0 its net charge is -18 . Hydrophobic interactions strongly contribute to the affinity of organic solutes for BSA; simultaneous contributions exist from electrostatic interactions, steric effects, hydrogen bonding and charge-transfer processes.

Mobile phases containing this chiral selector have been employed for the resolution of a broad variety of racemic compounds on silanized silica plates. Eluents were prepared by dissolving BSA (Serva, Heidelberg,

Figure 1 Structure of (2*S*,4*R*,2'*RS*)-*N*-(2'-hydroxydodecyl)-4-hydroxyproline.

FRG), fraction V, pH 5.2 or 7.0, in different buffer systems and then adding the desired amount of 2-propanol. The results suggest the use of acidic eluents to separate *N*-derivatized amino acids on wettable RP-18W/UV₂₅₄ (Macherey-Nagel) or RP-18W/F₂₅₄ (Merck) plates. On the other hand, the resolution of free amino acids increases with increasing eluent pH; in particular, the useful pH range on SIL C₁₈-50/UV₂₅₄ layers (Macherey-Nagel) is 9–10.

A prerequisite for optical discrimination is the presence of aromatic as well as polar groups in the solute. The existence of stereospecific binding sites on albumin is well known (i.e. tryptophan and warfarin) and it is believed that this binding occurs at a number of relatively defined regions. Two independent non-cooperative types of sites (chiral and achiral) coexist on the protein; the retention mechanism is partially in accord with that proposed on columns packed with immobilized BSA since in TLC albumin is used as a mobile-phase additive.

Retention and Resolution Data

In this article the contribution of chiral TLC to enantiomeric separations is surveyed, emphasizing the versatility of the method but without discussing the chiral recognition mechanism; this aspect has been examined elsewhere and in other parts of this Encyclopedia.

Amino Acids and Their Derivatives

A broad variety of racemic amino acids has already been resolved by chiral TLC. Table 1 summarizes the analytical separations achieved in this field on 20 cm × 20 cm Chiralplates (Cat. No. 811058, Macherey-Nagel; thickness 0.25 mm). The separations can be easily transferred to the 10 cm × 10 cm HPTLC-CHIR plates with concentrating zone since they are precoated with the same chiral selector.

With eluents A, B and C, 2 µL of a 1% solution of the racemates in methanol or methanol–water and with eluent D, 2 µL of a 0.5% solution of the racemates in 0.1 mol L⁻¹ hydrochloric acid–methanol 1 : 1 were applied to the plates. Migration time increases from 0.5 h (eluent A) to 1.5 h (eluent C). Detection was performed by dipping the plates for 3 s in a 0.3% ninhydrin solution in acetone and then heating at 110°C for *c.* 5 min. Red spots appear on a white background.

The amount of solute applied to the plates (10–20 µg) is an order of magnitude greater than that generally employed in TLC; the use of HPTLC-CHIR layers improves the sensitivity of the method.

Thus far, 84 proteinogenic and nonproteinogenic amino acids have been separated without derivatization using mostly methanol–water–acetonitrile (50 : 50 : 200, v/v/v) as eluent. Usually the *D* enantiomer is the more retained. Racemic serine shows low resolution, while threonine and basic amino acids have not been resolved as yet.

The separations of enantiomeric amino acids reported in Table 2 using a variety of chiral selectors are very interesting since they also include the unresolved compounds mentioned above. Round, compact spots are generally obtained on silica gel plates eluted with 2-*O*-[(*R*)-2-hydroxypropyl]- β -cyclodextrin solutions as deduced from *R_s* values which are equal to or higher than the α value for all the amino acids with the only exception of *DL*-citrulline (*R_s* = 0.94). Visualization is performed by spraying the plates with a salicylaldehyde solution (1.5 g) in 100 mL toluene and then heating at 50°C for 10 min (yellow spots).

Table 3 gives the performance of cellulose plates, which are very effective in resolving racemates of aromatic and basic amino acids. Home-made layers of microcrystalline cellulose powder (commercially available from Merck, and Fluka) can be obtained with optimal homogeneity by spreading an aqueous suspension with about 25% chiral material. The plates are dried at room temperature and do not require activation before use. Polar mixtures (i.e. ethanol–pyridine–water) are the best eluents since they separate enantiomers as efficiently as an aqueous solvent (i.e. 0.1 mol L⁻¹ NaCl) but give rise to more compact spots.

Chiralplates were very effective in resolving racemates of *N*-alkyl, *N*-carbamyl and *N*-formyl amino acids and of several dipeptides (Table 4). It is worth noting that the dipeptide with the C-terminal *L*-configuration always has a higher retention than the one with the C-terminal *D*-configuration. Some racemic dipeptides were also resolved on microcrystalline cellulose with pyridine–water (2 : 1 or 4 : 1) and on SIL C₁₈-50/UV₂₅₄ plates using BSA as chiral mobile phase additive.

Derivatization of amino acids may be used to improve chiral recognition, detectability and sensitivity of the method and to label amino acids residues of peptides and proteins, especially the *N*-terminal amino acid. Dimethylaminonaphthalenesulfonyl (dansyl) amino acids form when primary and secondary amino acids react with dansyl chloride, generating strongly fluorescent compounds. The best chromatographic conditions for their separation are reported in Table 5. The most complete study, performed on KC18 F plates (Whatman) using β -CD as chiral agent, concerns the racemates of 26

common and uncommon dansyl (Dns) amino acids. Similar results can be obtained on 10 cm \times 10 cm SIL C₁₈-50/UV₂₅₄ layers with the same eluents but with lower migration times. Some enantiomeric Dns-amino acids such as Lys, Met, Nva, Pro and aromatic compounds show low selectivity coefficients with β -CD. Therefore, it can be useful to resolve these racemates on RP-18W/UV₂₅₄ plates with eluents containing BSA since very high α values have been achieved.

Other *N*- and *C*-terminal substituents studied by chiral TLC include 2,4-dinitrophenyl (DNP), 3,5-dinitro-2-pyridyl (DNPy), 3,5-dinitrobenzoyl (DNB), *o*-nitrophenylsulfenyl (*o*-NPS), 9-fluorenylmethoxycarbonyl (FMOC), methylthiohydanthoin (MTH), phenylthiohydanthoin (PTH), *t*-butoxycarbonyl (*t*-BOC), carbobenzoxy (CBZ), phthalyl, acetyl, *p*-nitroanilide (pNA) and β -naphthylamide (β NA) (Table 6).

The maximum ΔR_F for the enantiomers of FMOC amino acids was obtained at different concentrations of 2-propanol. It is worth noting that this is the first

time optical isomers have been separated with eluents containing BSA in the presence of very high levels (12–36%) of organic modifier. The resulting spots have the shape of a reversed triangle. FMOC-DL-Asn and FMOC-DL-Gln are not resolved. The order of retention of the *D* and *L* forms of the different compounds is variable. The *D* forms of FMOC-Pro, FMOC-Trp and FMOC-Met are more retained than the *L* forms, whereas the opposite is noted for the other amino acids. This behaviour is also shown from DNP-amino acids and other *N*-derivatives.

Most DNP, DNPy and DNB-DL-amino acids are resolved on RP-18W/UV₂₅₄ plates with 0.1 mol L⁻¹ acetate buffer solutions containing 2% isopropanol and different BSA concentrations (2–6%) but few of them show chiral separation with phosphate buffer (0.05 mol L⁻¹ potassium dihydrogen phosphate + 0.05 mol L⁻¹ disodium hydrogen phosphate), an eluent of higher pH (6.86) than that previously used. Enantiomeric DNPy-Ala, DNPy-Nva and DNP-Eth(O₂) are completely separated at low

temperature (10°C) and pH values (0.5 mol L⁻¹ acetic acid) where their retention by the layer is sufficient. The unresolved racemates include DNP γ -Ser, DNP-Asp, DNP-Glu and DNP γ -Trp. The first three amino acids are markedly polar and are only slightly retained by silanized silica gel plates, even when eluted with acidic solution; this may be the reason for their not being resolved. In general, planar chromatography clearly separates the enantiomers of *N*-derivatized hydrophobic amino acids.

The complete resolution of DNP γ -DL-Trp is obtained on layers of SIL C₁₈-50/UV₂₅₄ with β -CD as chiral agent.

The optical isomers of PTH-amino acids are sensitive to light and readily racemize. Racemization of these optical active derivatives is observed on silanized silica gel plates with acidic eluents. MCTA plates may be useful since they are able to separate enantiomeric MTH-Phe, MTH-Tyr, MTH-Pro and PTH-Pro with neutral aqueous–alcoholic eluents.

Among C-terminal substituents, the enantiomeric β NA derivatives of amino acids were well separated on silanized silica gel plates with β -CD as

mobile phase modifier while pNA derivatives show discordant results. In fact, DL-Leu-pNA is fully resolved but DL-Ala-pNA failed since the latter optical antipodes do not form inclusion complexes of sufficient stability with β -CD. In addition, BSA seems efficient in the enantioseparation of pNA derivatives.

α -Hydroxycarboxylic Acids

Table 7 reports the separation and resolution data for aliphatic and aromatic DL- α -hydroxycarboxylic acids on HPTLC-CHIR plates with concentrating zone where the selectivity coefficients appear to be higher than those obtained on Chiralplates using the same eluent (dichloromethane–methanol, 45 : 5 v/v). Vanadium pentoxide may be used for detection of aromatic and aliphatic compounds. The oxide (1.82 g) is dissolved in 30 mL of 1 mol L⁻¹ sodium carbonate by ultrasonic bath and, after cooling, 46 mL of 2.5 mol L⁻¹ sulfuric acid and acetonitrile to 100 mL are added. Plates dipped in this solution and allowed to stand at room temperature give blue spots on a yellow background. All racemates studied were

completely resolved, the D forms being the most retained.

Acidic and Basic Drugs

The enantiomers of basic β -blocking drugs can be separated on HPTLC DIOL F₂₅₄ plates (Merck) with *N*-CBZ-Gly-L-Pro (or similar chiral agents) in the mobile phase, while the separation of the same drugs, derivatized with (R)-(-)-1-(1-naphthyl)ethyl

isocyanate in dichloromethane, has been performed on HPTLC-NH₂ F₂₅₄ plates chemically bonded with *N*-(3,5-dinitrobenzoyl)-*R*-(–)- α -phenylglycine (DNBPg) and eluted with different mixtures of *n*-hexane/isopropanol.

Interesting separations of racemates with a β -aminoalcohol structure (i.e. ephedrine and norephedrine, and β -blockers) can be achieved on MCTA plates after their cyclization with phosgene to form 5-substituted oxazolidinones.

$$^a hR_F = R_F \times 100.$$

Many acidic drugs (Figure 2) are resolved as 3,5-dinitroanilyl (DNAn) derivatives on precoated HPTLC-NH₂ F₂₅₄ plates derivatized with *R*-(–)-1-(1-naphthyl)ethyl isocyanate (Table 8). Although the naphthylethyl chromophore has a high UV adsorptivity, the detection problems found on plates bonded with DNBPg were not observed.

High selectivity coefficients are obtained for un-derivatized acidic drugs on MCTA and diphenyl-F plates eluted with aqueous–organic solutions containing, in the latter case, a chiral macrocyclic antibiotic (vancomycin).

Other pharmaceuticals resolved include bendroflumethiazide, coumachlor, mephentoin, oxindanac benzyl ester, warfarin, chlorowarfarin, hexobarbital, oxazepam, lorazepam, norphenylephedrine, hyoscyamine and colchicine.

Flavanones

Flavanones occur in nature and have been isolated in an optically active form. They contain only hydroxyl and methoxy groups and differ from one another in the number and/or position of such substituents (Table 9).

With the exception of glycosides, 5-methoxy-, 7-hydroxy- and 5-hydroxy-7-methoxyflavanone, the

enantiomers of the tested compounds can be separated by at least one of the chiral phases reported in Table 10.

In the series of flavanones no chiral discrimination was observed on MCTA plates for racemic 2'-hydroxy-, 4'-hydroxy- and 4'-methoxyflavanone in contrast to polysubstituted compounds. Partial resolution was obtained for flavanone, 6-methoxy- and 6-hydroxyflavanone. Two successive developments with the same eluent (ethanol–water, 80 : 20 v/v) effectively improves the separation of these racemates on MCTA layers.

The addition of β -CD to the mobile phase permits separation of enantiomeric flavanone and its 2'-hydroxy-, 4'-hydroxy- and 4'-methoxy derivatives.

Albumin is able to resolve racemic polysubstituted flavanones and 2'-hydroxyflavanone. Alkaline mobile phases must be used for their separation.

Miscellaneous Compounds

The chiral NMR solvating agent 1-(9-anthryl)-2,2,2-trifluoroethanol (TFAE) has been separated by a variety of chromatographic techniques and has become a reference compound for testing new optically active selectors. For example, α values of 2.02 and 2.34

^a $hR_F = R_F \times 100$.^b $\alpha = (1 \div R_{F1} - 1)/(1 \div R_{F2} - 1)$.

were obtained, respectively, on OPTI-TAC F₂₅₄ (Antec) plates eluted with ethanol–water 80 : 20 (v/v) and on SIL C₁₈-50/UV₂₅₄ layers using 6% BSA in 0.05 mol L⁻¹ sodium tetraborate containing 20% isopropanol (pH 9.75) as mobile phase.

(\pm)-1-(9-Fluorenyl)ethanol an analogue of TFAE, was also resolved on home-made MCTA plates eluting with 2-propanol–water 80 : 20 (v/v) (α = 2.24).

The separation of chiral compounds with restricted rotation, as in the case of binaphthyl type of substances, can be effected both on CSPs and with CMPs. The first technique requires the use of MCTA plates to resolve (\pm)-1,1'-binaphthyl-2,2'-diamine (α = 1.99) while the latter involves chiral mobile

phases containing BSA for the separation of (\pm)-1,1'-bi-2-naphthol (α = 2.15) and (\pm)-binaphthyl-2,2'-diyl-hydrogen phosphate (α = 4.65).

The enantiomeric separations of synthetic pyrethroids, such as alfamethrin and fenpropathrin, on home-made MCTA plates with ethanol–water 80 : 20 (α = 1.37 and 1.20, respectively) should be noted since their optical antipodes have different rates of degradation and biological activity towards animals and plants.

The resolution of racemic fenoxaprop-ethyl on the above-mentioned CSP (α = 1.52, isopropanol–water 80 : 20) is interesting since chlorophenoxyalkyl carboxylic acids and esters are widely used herbicides.

^aMigration distance, measured from concentrating zone, 13 cm; visualization: (a) the plates were dipped in MnCl_2 -sulfuric acid heating up to 120°C for 30 min for aromatic α -hydroxycarboxylic acids; (b) the plates were dipped for 2 s in vanadium (V)-sulfuric acid solution and dried at room temperature for c. 45 min for aromatic and aliphatic α -hydroxycarboxylic acids.

^b $hR_F = R_F \times 100$.

^c $\alpha = (1 \div R_{F1} - 1)/(1 \div R_{F2} - 1)$.

^dEluents: A = dichloromethane/methanol 45 : 5 (v/v); B = 0.05 mol L⁻¹ KH_2PO_4 in a methanol-acetonitrile-water 50 : 50 : 200 (v/v/v) mixture; C = 0.1 mol L⁻¹ LiCl in a dichloromethane-ethanol 85 : 15 (v/v) mixture; D = acetonitrile-water 3 : 2 (v/v).

The use of mobile phases containing β -CD seems to be particularly appropriate for the resolution of racemic *S*-(1-ferrocenyl-2-methylpropyl)thioethanol and *S*-(1-ferrocenylethyl)thioethanol ($\alpha = 1.43$ and 1.18, respectively).

Many noncharged solutes with a carbonyl group close to the stereogenic centre can be resolved on MCTA plates (benzoin, benzoin methyl ether, 2-phenylbutyrophenone, 2- and 3-methylindanone, 2-phenylcyclohexanone, 2-phenylcycloheptanone and 2-oxazolidone derivatives).

Quantitative Analysis of TLC-Separated Enantiomers

TLC is generally coupled with spectrophotometric methods for quantitative analysis. Quantification can be achieved by *in situ* densitometry or after extraction of solutes from the scraped layer. The evaluation of detection limits for separated enantiomers is essential because precise determinations of trace levels of D- or L-enantiomer in an excess of the other is becoming more and more important.

On Chiralplates and HPTLC-CHIR layers, densitometry can be performed after postchromatographic derivatization of compounds with ninhydrin or vanadium pentoxide. Successful separation of amino acids on Chiralplates depends on the hydrochloric acid content of the applied solution (usually a methanol-0.1 mol L⁻¹ HCl 1 : 1 (v/v) mixture).

Remission-location curves of DL- α -hydroxycarboxylic acids, achieved in reflectance mode with a Shimadzu CS930 scanner or a Desaga CD60 densitometer, show that only enantiomers with high ΔR_F values (≥ 0.10) can be baseline resolved on 10 cm \times 10 cm HPTLC-CHIR plates (Figure 3). On such plates, L-2-hydroxy-3-phenylpropionic acid spiked with 1% D enantiomer ($\Delta R_F = 0.12$) gives rise to partially resolved peaks but the D isomer is still visible. With respect to small particle size HPTLC-CHIR layers, higher R_F values have been obtained on 20 cm \times 20 cm Chiralplates owing to migration distances being twice as long (α values being equal).

The remission-location curves of Figure 4 and the calibration line for L-phenylalanine (Figure 5) demonstrate that quantitative determinations of L-isomer in D-phenylalanine on Chiralplates ($\Delta R_F = 0.10$) are possible in a working range of 0.04–0.4 $\mu\text{g/spot}$, that is 0.1–1%. Further determinations include 0.1% D-*t*-Leu in L-*t*-Leu ($\Delta R_F = 0.11$), 0.1% L-5,5-dimethylthiazolidine-4-carboxylic acid in the D-enantiomer ($\Delta R_F = 0.14$) and 1% D-hydroxyphenylalanine in the L-enantiomer.

The peak of 1% Dns-D-Glu in L-enantiomer is visible on 20 cm \times 20 cm RP-18 plates (Merck) impregnated with a solution of 8 mol L⁻¹ N,N-di-*n*-propyl-L-alanine and 4 mmol L⁻¹ cupric acetate.

On 10 cm \times 20 cm cellulose plates L-tryptophan spiked with 5% D-enantiomer gives rise to partially resolved peaks owing to the small ΔR_F value (0.06).

The use of MCTA allows the determination of enantiomeric mixtures in the ratios 100 : 1 and 200 : 1. (*S*)-2,2,2-Trifluoro-1-(9-anthryl)ethanol can be detected at 1% level in (*R*) enantiomer on OPTI-TAC F₂₅₄ plates eluted with ethanol-water 80 : 20 ($\Delta R_F = 0.17$; length of run 10 cm). Baseline-resolved

Figure 2 Structure of acidic drugs.

peaks ($\Delta R_F = 0.10$) were obtained for the two atropisomers of 1,1'-binaphthyl-2,2'-diamine on 20 cm \times 20 cm home-made MCTA plates at 100 : 1 ratio. Partial resolution only was observed at a ratio of 200 : 1, but the *S* isomer is still visible (Figure 6).

Conclusions

Chiral TLC plays a significant role both in economical routine analyses and in determination of optical purity of individual antipodes. Detection limits of $\geq 0.1\%$ D- or L-isomer can be currently achieved.

Less work is being carried out on chiral TLC than on column chromatography, even though the two techniques may give complementary results and TLC has advantages such as low cost and easy evaluation of the tests.

Future possibilities of chiral TLC include:

1. the synthesis of enantiomeric derivatives that are easier to resolve and more sensitively detected than those so far investigated;
2. the availability of layers prepared from new cellulose derivatives and, in addition, the availability of more versatile MCTA plates using highly crystalline and homogeneously sized material;

3. more extensive application of normal-phase chromatography with a chiral mobile phase additive (DIOL plates are particularly advisable);
4. the use of eluents containing new chiral selectors in reversed-phase systems, which is the technique most widely used for enantioseparations.

CITRUS OILS: LIQUID CHROMATOGRAPHY

P. Dugo, Università di Messina, Messina, Italy

Messina, Italy

Copyright © 2000 Academic Press

Citrus essential oils are very complex matrices which contain numerous compounds of different chemical classes. These compounds are generally divided into two fractions: the volatile fraction, which is the most representative, and ranges between 85 and 99% in the different cold-pressed citrus oils, and the non-volatile residue, which ranges between 1 and 15%.

The development of new instrumental analytical techniques, mainly chromatographic, has allowed the characterization of citrus essential oils to become more precise.

Gas chromatography is an essential tool for the study of the volatile fraction, while liquid chromatography (thin-layer chromatography (TLC) and high-performance liquid chromatography (HPLC) combined with spectral absorption and fluorescence measurements) is widely used for the study of the composition of the non-volatile residue. This fraction consists largely of oxygen heterocyclic compounds (coumarins, psoralens (furanocoumarins) and polymethoxylated flavones) that exhibit strong absorption in the ultraviolet region (λ_{max} about 315 nm).

The presence of coumarin compounds is widespread in plants of the *Rutaceae* family to which the citrus species belong. Their presence is qualitatively and quantitatively different in the different citrus oils, so knowledge of the oxygen heterocyclic fraction may be useful to assess authenticity, the geographical origin and the possible adulteration of the oils.

Figure 1 shows the basic structures of the oxygen heterocyclic compounds present in citrus oils. In the numbered position, coumarins and psoralens may contain hydroxyl, methoxyl, isopentenyl, isopentenyl, geranyloxy groups; polymethoxylated flavones contain methoxyl groups. Table 1 lists the oxygen heterocyclic compounds identified in citrus oils.

TLC Separations

The literature from the 1930s to the end of 1970s reports numerous TLC separations of non-volatile residue of citrus oils with the aim of isolating the

components. Often these components were not identified before and were responsible for ultraviolet (UV) absorption. Knowledge of the chromatographic characteristics and the chemical structures of these compounds was considered very important in order to determine the authenticity of the oils. In fact, valuable cold-pressed oils may be adulterated with less valuable cold-pressed or distilled oils. In these cases the presence and/or the content of some oxygen heterocyclic compounds may be useful to determine the kind and also the degree of adulteration.

Many methods developed for the TLC analysis of oxygen heterocyclic compounds of citrus oils used silica gel as a stationary phase, and mixtures of hexane or cyclohexane with variable amounts of ethyl acetate as mobile phases. For example, a paper of 1965 reports the separation of coumarins of many citrus oils by TLC, obtained on silica gel plates, using mixtures of hexane with variable amounts (25–70%) of ethyl acetate, according to the different polarity of the components. The spots were detected by UV absorbance at 254 and 366 nm. The components were also isolated from the plates, extracted from silica gel and analysed by UV spectroscopy. Table 2 provides chromatographic and spectroscopic data for the oxygen heterocyclic compounds of lemon, bergamot, mandarin, sweet orange and bitter orange. Identification was carried out by comparison of R_f values and spectroscopic data with those of standard compounds.

Figure 1 Structures of oxygen heterocyclic compounds present in citrus oil.

psoralen; (7) 8-geranyloxypsoralen; (9) citropten; (12) oxypeucedanin; (14) byakangelicol. These main components were isolated by preparative column chromatography, crystallized and analysed by spectroscopic methods [infrared (IR), UV, nuclear magnetic resonance (NMR)].

Figure 2 TLC separation of coumarins and psoralens of lemon oil. Eluent: hexane–butyl acetate, 65 : 35 (A) and 75 : 25 (B). (Reproduced with permission from Glandian R, Corneteau H, Drouet S and Rouzet M (1978) *Plantes, Medicinales et Phytoterapie*, 12 (2), 112–122.)

TLC separation of citrus oils has also been coupled with detection by *in situ* fluorimetry. This method shows the advantages of both the techniques, and a good selectivity and sensibility. As an example, the quantitative determination of 5-geranyloxy-7-methoxycoumarin and 5,7-dimethoxycoumarin (citropten) present in bergamot, lime and lemon oils, and the qualitative profile of citrus oils have been obtained by measuring the fluorescence and the fluorescence quenching profiles directly on the TLC plates. Emission monochromator wavelength settings of 403, 440 and 490 nm were used to obtain the various fluorescence emission profiles. An excitation wavelength of 272 nm and an emission wavelength of 520 nm were used to obtain the fluorescence quenching profile. These values correspond to the maximum of excitation and emission of the fluorescent indicator in the adsorbent layer.

Analytical and preparative TLC of coumarins and psoralens have been widely used. Some of the advantages of this technique are its simplicity and low cost. Disadvantages may be the difficulty of controlling the flow rate, the low resolution, the low reproducibility and the long time required for development. In recent years various modern planar chromatographic methods have been reported for the analysis of coumarins. Some of these methods use a new forced-flow TLC technique, developed by Tyiháck and co-workers between 1979 and 1981, called OPLC (overpressured layer chromatography). This new planar technique combines the advantages of classical TLC and HPLC: shorter analysis times, lower solvent consumption, simultaneous analysis of a large number of

samples, the possibility of performing isocratic or gradient elution, control of the flow rate and higher efficiency. The literature reports some examples of the applications of OPLC technique to the analysis of coumarins and psoralens.

As shown by Härmälä *et al.* in 1990, TLC separation methods can be improved by use of two-

dimensional high performance TLC (2D TLC). **Figure 3** shows the one-dimensional (A) and the two-dimensional (B) OPLC development of 16 coumarins.

Another way to increase the efficiency of TLC separation is by using the stepwise gradient technique. By increasing the strength of the mobile phase, the separation of compounds with similar R_f values is

improved. **Figure 4** shows an example of gradient TLC of coumarins and psoralens of some plant extracts.

Tables 3 and 4 provide results obtained for the OPLC analysis applied to seven citrus oils, using silica gel 60 F254 HPTLC plates with impregnated edges (flow rate: 0.7 mL min⁻¹). Detection was by UV at 366 nm; time of analysis: 10 min. Because of its advantages, this method has been proposed as a rapid, preliminary check to evaluate the authenticity of citrus oils.

HPLC Separations

As well as TLC methods the literature reports numerous qualitative and quantitative methods for the analysis of coumarins and related compounds by both normal- and reversed-phase HPLC. Detection is commonly performed by UV absorbance, but methods which use the highly selective and sensible fluorescence detector are also reported.

Two important papers are those of McHale and Sheridan of 1988 and 1989 in which the authors developed normal-phase HPLC methods for the analysis of the most common citrus oils, making huge progress in the identification and in the quantitative determination of oxygen heterocyclic compounds. The first paper refers on the composition of

Table 5 Composition of oxygen heterocyclic fraction of cold-pressed Sicilian lemon oil reported by McHale and Sheridan (1988)

Peak no.	Component	Concentration mg L ⁻¹ (ppm)
1	Bergamottin	2200
2	5-Geranyloxy-7-methoxycoumarin	1600

cold-pressed lemon oil. **Figure 5** shows the HPLC chromatogram in which 14 components were detected and quantitatively determined. The experimental conditions are shown in the figure legend. **Table 5** reports the quantitative results.

These workers identified and quantified not only the main components, but also those present in lower amounts. Moreover, they analysed commercial samples of lemon oils, and demonstrated the validity of the method to detect some adulterations practised to increase the UV absorbance of oils previously diluted with distilled ones. The method allows for the detection of *p*-dimethylaminobenzoate, grapefruit oil and/or lime oil, that are the most common substances used to increase UV absorbance. The paper of 1989 shows normal-phase HPLC chromatograms of ber-

*Compounds previously unknown in cold-pressed lemon oil.

Citrus oils that show a quite complex composition of the oxygen heterocyclic fraction are difficult to analyse either by normal- or reversed-phase HPLC with a single column. In these cases the 'column switching' technique can be useful to improve the separation of those critical peaks. This technique has been applied successfully to the analysis of bitter orange and grapefruit oils, which show a very similar composition, to separate 17 components and, in particular, to the couple meranzin–isomeranzin. **Figures 11** and **12** show the results obtained, together with the experimental conditions and peak identification.

Most of the data found in the literature refer to the characterization of bergamot oil, and in particular to the determination of 5-methoxypsoralen (bergapten), which is known to have a higher phototoxic action than other psoralens found in citrus oils. Bergamot oil is widely used in the cosmetic and pharmaceutical

**Figure 11** HPLC chromatogram of oxygen heterocyclic components of cold-pressed bitter orange oil. For peak assignment and experimental conditions see Figure 12. Figure 12 HPLC chromatogram of oxygen heterocyclic components of cold-pressed grapefruit oil obtained in the following conditions: μ -porasil column 30 cm \times 3.9 mm internal diameter (10 μ m) for the first 12 min, then the flow was switched to a second column, Zorbax silica 25 cm \times 4.6 mm internal diameter (7 μ m). Eluent A, hexane-ethyl acetate, 9 : 1; eluent B, hexane-ethyl alcohol, 9 : 1. 2–95% B over 23 min (2–25 min) with a concave gradient, then 20 min isocratic 95% B, flow rate 1.6 mL min⁻¹; sample volume 20 μ L (5% solution of oil in hexane-ethyl acetate, 75 : 25); detection by UV absorbance at 315 nm. Peak assignment: (1) bergamottin; (2) auranpten; (3) osthol; (4) bergapten; (5) epoxybergamottin; (6) epoxyaurapten; (7) unknown coumarin; (8) meranzin; (9) isomeranzin; (10) unknown coumarin 2; (11) tangeretin; (12) 3,3',4',5,6,7,8-heptamethoxyflavone; (13) nobiletin; (14) tetra-*O*-methylscutellarein; (15) unknown coumarin; (16) epoxybergamottin hydrate; (17) meranzin hydrate; (i.s.) internal standard, coumarin. (Reproduced with permission from Dugo P, Mondello L, Stagno d'Alcontres I, Cavazza A and Dugo G (1997) *Perfumer and Flavorist* 22: 25–30.)

industries. Usually, genuine cold-pressed bergamot oil contains about 2000–3000 ppm of bergapten, but many industrial processes have been developed with the aim to reduce its concentration to values of only a few parts per million. The oils so obtained are known as 'bergapten-free' oils. Table 8 summarizes some of the TLC and HPLC methods proposed for the quantitative determination of bergapten in bergamot oil.

HPLC–MS

To obtain more information on the nature and the structure of the components analysed by HPLC, an MS detector can be coupled on-line to the HPLC system. An innovative interface for the HPLC–MS coupling is the API (atmospheric pressure ionization), that differs from the traditional interfaces because the ionization takes place at atmospheric pressure.

The API technique can use two different interfaces, the electrospray (ES) or the atmospheric pressure chemical ionization (APCI), and can give different information than those obtained with conventional LC–MS interfaces. Both the techniques are classified as 'soft' ionization methods. By varying the voltage of the sample cone it is possible to obtain different degrees of fragmentation.

The HPLC–MS technique with the APCI interface has been applied to the analysis of coumarins of citrus oils to confirm the identification of some components or to obtain more information for those not identified yet. As an example, Figure 13 shows the HPLC–UV chromatogram of a cold-pressed bergamot oil, compared to the full scan HPLC–MS chromatogram acquired at different cone voltage values.

Figure 14 shows the MS spectra obtained at different cone voltage values for one of the components of bergamot oil (bergamottin). As can be seen, at the lower cone voltage value the $(M + H)^+$ ion is visible, while at higher values additional fragmentation occurs.

The HPLC–MS technique allowed the confirmation of the presence of oxygen heterocyclic compounds previously not identified in bergamot oil, such as tetra-*O*-methylscutellarein and sinensetin. Figure 15 shows the HPLC–UV chromatogram at cone voltage value of 20 V, and the extracted chromatogram at m/z 243 and 273, corresponding to the $(M + H)^+$ ions of tetra-*O*-methylscutellarein and sinensetin.

Supercritical Fluid Chromatography (SFC)

A few applications of supercritical fluid chromatography (SFC) to the analysis of citrus coumarins have been reported. Even though this technique is less popular in the analysis of citrus coumarins, it is interesting to compare the results obtained by SFC to those obtained by HPLC. Figure 16 shows a normal phase HPLC chromatogram of the polymethoxylated flavones of sweet orange oil (A), compared to the packed SFC chromatogram obtained for the same oil (B).

Table 9 provides the chromatographic conditions under which the two analyses have been carried out. Both the analyses allowed a complete separation of the six polymethoxylated flavones (PMFs) known to be present in sweet orange oil. The SFC analysis was completed in less than 6 min, while the HPLC analysis took more than 25 min. This represents a reduction in the analysis time by a factor of four. Quantitative results obtained with the SFC method compared well with those obtained with the HPLC method.

Table 8 TLC and HPLC methods for the analysis of bergapten in bergamot oil.

Technique	Stationary phase	Mobile phase	Detection method	Flow rate	Sample
HPLC	2 cm × 2.3 mm internal diameter stainless steel tubing packed with 37-50 Corasil II	Hexane–chloroform, 75 : 25	UV abs. at 254 nm	0.25 mL min ⁻¹ <i>P</i> = 100 psi	10 µL of a solution of 0.05 g of oil in 10 mL of CHCl ₃
TLC	Silica gel plates F-254	Isoctane–ethyl acetate, 83 : 17	UV abs. at 254 nm		Oil diluted 1 : 10 in CHCl ₃
TLC	Silica gel plates F-254 (20 µm)	Cyclohexane–ethyl acetate–acetic acid, 80 : 20 : 2	UV abs. at 254 and 366 nm		
TLC	10 × 10 cm Silica gel HPTLC plates 60 F-254 (5 µm)	Petroleum ether or benzene followed by cyclohexane–ethyl acetate, 75 : 25	Densitometer at 254 or 308 nm or Fluorescence (λ_{exc} 330 nm, λ_{em} 450 nm)		
TLC	10 × 10 cm RP 18 TLC plates (7 µm)	Methanol–water, 80 : 20	Densitometer at 254 or 308 nm		Oil diluted in methanol
HPLC	Lichrosorb Si 60 (5 µm) 23 cm × 4.35 mm internal diameter	Heptane–isopropanol, 93 : 7	UV abs at 254 nm	0.85 mL min ⁻¹ , <i>P</i> = 23 bar	
HPLC	Lichrosorb RP 18 (5 µm) 17 cm × 4.35 mm internal diameter	Methanol–water, 9 : 1	UV abs at 254 nm	1.1 mL min ⁻¹ , <i>P</i> = 24 bar	
HPLC	Lichrosorb Si 60 (5 µm) 25 cm × 4.6 mm internal diameter	Hexane–ethyl acetate–propan-2-ol, 88 : 10 : 2 (isocratic)	UV absorbance at 305 nm	1 mL min ⁻¹	Undiluted for oil with less than 40 mg L ⁻¹ of bergapten, or diluted in the range 20–40 mg L ⁻¹ with CHCl ₃ · 20 µL inj

**Figure 13** (A) HPLC–UV chromatogram and (B), (C) and (D) total ion current (TIC) HPLC chromatograms acquired at cone voltage values of 60, 40 and 20 V, respectively, of coumarin fraction of a genuine bergamot essential oil. Conclusion

Citrus essential oils show a characteristic composition of their oxygen heterocyclic fraction. These components make it possible to differentiate the individual oils and to detect mixtures or mutual contamination. Quantitative analysis is often necessary to assess authenticity or geographical origin of an oil. Sometimes, quantitative analysis has to be preceded by isolation of single components for structure elucidation and also to obtain pure standard compounds to be used for preparation of standard solutions, since they are not always commercially available. Moreover, these components possess numerous pharmacological activities, so isolation may be necessary for testing specific biological activities.

Both analytical and preparative analyses can be carried out with planar and column liquid chromatographic methods (TLC, OPLC, HPLC). Usually, the preparative separations, that may be long and laborious, are followed by further purification steps and by spectroscopic analyses for identification.

Working with natural products, efficient detection and rapid characterization are often essential. Fur-

thermore, the achievement of structural information on unknown constituents of a complex mixture is a strategic element for guiding an efficient and selective isolation procedure.

A big advantage can be achieved by using hyphenated techniques. In the last few years, LC-MS is becoming more and more popular, because of the introduction of API (atmospheric pressure ionization) techniques as a means for mass spectrometric sample introduction. This interface permits a highly selective and sensitive detection method, to be obtained and use of HPLC-MS in routine analysis. Recently, LC-NMR has been introduced as another powerful complementary technique for on-line structural identification, even though it is much less sensitive than LC-MS. Application of planar chromatography coupled with mass spectrometric (MS) or Fourier transformed infrared (FT-IR) have also been developed.

Looking to the future, it is reasonable to expect a much wider use of hyphenated techniques that will allow the rapid structural determination of constituents of complex matrices requiring only a small amount of samples, and the use of shorter HPLC columns packed with smaller particles that will

CLINICAL APPLICATIONS

Capillary Electrophoresis

Introduction

The area of clinical applications of capillary electrophoresis (CZE) is such a rapidly growing field that it would be impossible here to cover it in detail. We thus offer a list of major reviews to which the reader is referred for a more comprehensive coverage of the

literature. Such reviews can be divided into:

1. Broad-coverage reviews, such as those of Lehmann *et al.* (1997), Perrett (1999; CZE in clinical chemistry) and Guzman *et al.* (1997; dedicated also to on-line analyte concentration and micro-reaction). Also of interest are special issues of the *Journal of Chromatography B* dedicated to CZE in the life sciences (Krstulovic 1997) and of *Electrophoresis* devoted to CZE in the clinical sciences (Landers 1997) and in forensic science (McCord, 1998).
2. Specialized reviews, such as those of Thormann *et al.* (1996, 1997; drug analysis in body fluids); Lurie (1996; analysis of seized drugs), Hong and Baldwin (1997; metabolite profiling in human urine), Righetti and Gelfi (1997a,b, 1998; CZE of

DNA for molecular diagnostics), Jellum *et al.* (1996, analysis of urinary diagnostic metabolites and serum proteins), Lazaruk *et al.* (1998; genotyping of forensic short tandem repeat systems).

CZE: Some Basic Concepts Related to Clinical Chemistry

An important aspect of CZE relevant to clinical chemistry is the paradox by which one of the noted advantages of CZE, namely the small volume of the capillary, also leads to a significant drawback, i.e. the minute amount (3–10 nL) of sample introduced, which results in poor concentration limits of detection, one to two orders of magnitude lower than in high-performance liquid chromatography (HPLC). Thus, preconcentration techniques are often required for compounds present in very low concentrations in biological fluids. These include transient isotachopheresis, analyte stacking, field-amplified sample injection (all on-capillary techniques) or off-column preconcentration techniques, such as liquid-liquid or liquid-solid extraction. Alternative on-column methods include miniaturized solid-phase extraction with cartridges containing reversed-phase HPLC packing materials or with impregnated membranes. When analysing small analytes or drugs in sera, it is often necessary to deproteinize the sample. This can be efficiently achieved by extracting sera with 60% acetonitrile, which accomplishes two tasks: protein precipitation and analyte stacking upon electrokinetic injection because of the very low con-

ductivity of such a solution. Some areas of interest where CZE offers unique resolution and sample quantification are discussed below.

Drug Analysis

With the more efficient therapeutic application of various drugs and the necessity for screening and confirmation of drugs in body fluids for diagnostic and research purposes, there has evolved a need for reliable analytical procedures. CZE is becoming the method of choice for drug monitoring in body fluids, including plasma, serum, saliva and urine. Some relevant data are given in Tables 1–3.

Profiling Clinically Important Metabolites in Urines

There are approximately 300 known metabolic disorders many of which, if not treated, have serious and sometimes life-threatening consequences. Generally, the diagnosis of these disorders is made or confirmed by identification and quantification of characteristic metabolite(s) occurring in body fluids as a result of the particular enzyme deficiency involved in each disease. In addition, once the diagnosis has been made, the effectiveness of subsequent therapy can also be evaluated by analogous monitoring of the levels of the same metabolic markers. Recently, CZE has become an attractive tool for monitoring clinically important metabolic markers, including alditols, carbohydrates and amino acids, which can be profiled directly in urine with electrochemical (EC) detection at a copper electrode. EC detection allows sensitivity down to the femtomolar level and can be performed

following metabolites: orotic acid, pyroglutamate, adenylosuccinate and propionic acid, for the following diseases: HHH-syndrome (hyperornithinemia-hyperammonemia-homocitrullinuria), glutathione deficiency, adenylosuccinase deficiency and propionyl CoA carboxylase deficiency, respectively, can be found in Jellum *et al.* (1997).

Profiling Proteins in Biological Matrices

Separation and quantification of distinct proteins from biological matrices is another goal now being accomplished by CZE. A list of some major proteins of importance for clinical diagnosis is given in Table 5. In some cases, immunosubtraction can be an efficient way of quantifying some protein families by CZE. A typical example is the quantification of specific immunoglobulin subclasses by sequential immunosubtraction. The sample is exposed to five different Sepharose supports, each containing an immunoglobulin-specific binder. Three of them are specific for the heavy chains IgG, IgA and IgM and two are specific for the light chains κ or λ . After incubation and sedimentation, the treated samples and an untreated control are separated by CZE. Six electropherograms are generated per sample. The class and type of monoclonal component can be determined by overlaying electropherograms from before and after immunosubtraction.

Examples of Some Separations

It is quite difficult to compress in such a few pages the vast literature in the field of clinico-chemical applica-

tions of CZE. From our experience in DNA separations, we offer here a few examples pertaining to the screening for human genetic diseases. **Figure 1** displays the CZE analysis of a multiplex PCR for the

Figure 1 Simultaneous detection of $\Delta F508$, G542X, N1303K and 1717-1G \rightarrow A mutations in cystic fibrosis by CZE in polymer networks. Traces: A, patient carrying the mutations 1717-1G \rightarrow A and $\Delta F508$; B, patient affected by the G542X/N1303K mutations; A + B, artificial mixture of the amplified DNA fragments of patients A and B. Conditions: 100 μ m ID, 37 cm long capillary, filled with a viscous solution of linear 6% T polyacrylamide in 100 mmol L⁻¹ TBE (Tris-borate-EDTA) buffer, 10 μ mol L⁻¹ ethidium bromide, pH 8.3; Run at 165 V cm⁻¹ with detection at 254 nm; electrophoretic sample injection at 165 V cm⁻¹ for 8 s. Reprinted from Gelfi C, Righetti PG, Magnani C, Cremonesi L and Ferrari M (1994) *Clinica Chimica Acta* 229, 181–189, with permission from Elsevier Science.

simultaneous detection of four mutations, $\Delta F508$, G542X, N1303K and 1717-1G \rightarrow A in cystic fibrosis (CF). This is an interesting example, in that it offers a fast and reliable method for the simultaneous detection of mutations which are predominant in a given population. In Italy, a survey of 391 CF patients, originating from all geographical regions, revealed that $\Delta F508$ (53% of CF chromosomes), G542X (4%), 1717-1G \rightarrow A (4%) and N1303K (4%) are the most frequent mutations, accounting for 65% of all molecular defects pertaining to CF. **Figure 2** gives the CZE analysis for the Duchenne (DMD) and Becker (BMD) muscular dystrophies, which represent the two most common myopathies described to date. They are given the names of Chamberlain and Beggs since these two scientists proposed two PCR assays (each based on co-amplification of nine dystrophin gene exons) allowing for the detection of over 98% DMD/BMD deletions. Thus, a method attempting simultaneous analysis of DMD/BMD should offer unambiguous resolution and identification of 18 fragments ranging in size from *c.* 100–500 bp. This is in fact achieved in the lower trace of **Figure 2** (representing a healthy individual). The upper trace shows a patient affected by muscular dystrophy, in which four fragments (196, 202, 331 and 357 bp) are missing. We hope that these two examples, albeit limited,

provide an insight on the unique resolving power and capability of CZE as applied to problem solving in clinical chemistry.

Conclusions and Future Horizons

Compared with HPLC and gas chromatography, CZE has some distinct advantages, such as small sample size, minimal sample preparation, use of very small amounts of organic solvents and inexpensive chemicals, ease of buffer change and method development and low cost of capillary columns. Electrokinetic capillary assays are complementary to the widely employed immunoassays. For the widespread adoption of CE in routine laboratories, a number of improvements should be made. With the availability of instrumentation comprising multiple capillaries in parallel, sample throughputs comparable to those obtained in automated immunoassays should be possible. The same goal will be reached with the availability of chip-based instrumentation, i.e. CZE on a glass chip on which separation channels, a picolitre sample injector and solute detection are combined on an area of a few cm². In this approach, fluid flow is driven electrokinetically (thus via a plug, not a laminar flow) through a network of intersecting small channels fabricated on planar glass substrates

Figure 2 Screening for Duchenne (DMD) and Becker (BMD) muscular dystrophies by CZE in sieving liquid polymers. The upper trace represents the separation of 14 exons of modified deleted Chamberlains' and Beggs' mixed multiplex. The lower electropherogram shows the separation of 18 exons of modified nondeleted Chamberlains' and Beggs' multiplex. All runs were in a 32 cm long, 75 μm internal diameter capillary, filled with short-chain polyacrylamide, obtained by chain transfer at 70°C, in 89 mM TBE buffer, pH 8.3. Run: 165 V cm^{-1} with detection at 254 nm. Sample injection: 100 V cm^{-1} for 25 s. Reprinted from Gelfi C, Orsi A, Leoncini F, Righetti PG, Spiga I, Carrera P and Ferrari M (1995) *BioTechniques* 19, 254–263, with permission from Elsevier Science.

by photolithographic masking and chemical etching techniques and formed by bonding the etched substrate to a plain glass plate. Capillaries 30–70 μm wide, about 10 μm high and a few centimetres long have been shown to provide analytical runs in a few seconds.

Introduction

It is somewhat arbitrary to outline electrophoretic applications that are used in a routine clinical laboratory because they are highly dependent on the specificity of each application. Nowadays, a multitude of electrophoretic methods are routinely used in various clinical laboratories, according to the specific research being developed. More and more sophisticated methods are needed to resolve specific clinical problems, the reason why specialization of laboratories is mandatory in order to provide accurate results at the lowest possible cost. In addition, quality control is of major importance. Therefore, automation is progressively introduced in all the steps involved in the analytical process, and only a few manual methods will survive in the future. However, highly sophisticated electrophoretic techniques should be maintained and developed in a limited number of specialized laboratories, in order to resolve the different problems that are encountered in clinical medicine. Here, we present selected examples of electrophoretic techniques that are employed in the clinical laboratory.

Serum Protein Electrophoresis

Electrophoretic techniques for the separation of human serum proteins have been used for fifty years. Resolution has been improved by the use of support media such as paper, starch gel, cellulose acetate, agarose, and polyacrylamide gels, which have rendered electrophoretic methods very popular in the diagnostic area. However, many of those methods have remained labour intensive, being difficult to

automate. Serum protein electrophoresis is widely used in clinical laboratories, especially for the evaluation of changes in proteins associated with inflammation, liver or kidney diseases as well as for the detection and identification of paraproteins. Traditional clinical electrophoretic procedures are manual methods that use agarose gels or cellulose acetate membranes as the separation bed. Quantitation of the five major serum fractions is done by densitometric scanning of the gel or the membrane. Clinical interpretation is based on the alteration of the content of one or more of the five fractions. Agarose, as supporting medium for protein electrophoresis, has been reported to give better resolution as well as to allow better detection of paraproteins than is cellulose acetate. Semiautomated agarose electrophoresis and immunofixation can be performed with various commercially available systems. No differences between manual and semiautomated methods have been seen with respect to paraprotein identification.

Over the last few years, capillary zone electrophoresis (CZE) has emerged as a powerful new tool for rapid separation of various biopolymers, including proteins. Separation by this technique depends on the electrophoretic mobility of the analyte and the electroosmotic flow of the bulk solution, and can be easily automated. Direct quantitation of proteins via peptide bonds is possible using UV detection at 214 nm. Separation patterns obtained by CZE are similar to those obtained after densitometric scanning of cellulose acetate membrane electrophoresis or agarose gel electrophoresis. Recently, dedicated automated systems for the routine analysis of human serum proteins in clinical laboratories have become commercially available. High sample throughput is attained due to the presence of several fused-silica capillaries, which allow the simultaneous analysis of different samples. Several studies have clearly shown that the electrophoretic patterns and the clinical information obtained by CZE are comparable with the data obtained by classical methods. In addition, the method is also suited to detect monoclonal gammopathies. Multicapillary instruments have been

designed for automation of both routine serum protein electrophoresis and for monoclonal component typing by subtraction (immunofixation electrophoresis – immunosubtraction). In this latter technique, CZE is performed on the supernatant of serum samples that have reacted with Sepharose beads coated with an immunospecific binder (IgG, IgA, IgM, κ and λ). The low detection limit of the technique (0.5 g L^{-1} for IgG, 0.75 g L^{-1} for IgA and IgM) contributes to the ability of CZE to detect small monoclonal gammopathies.

Lipoprotein Analysis

The cardiac risk profile that is routinely measured in the clinical laboratory is an important indicator of susceptibility to the development of atherosclerosis. There is clearly a need to develop a more comprehensive cardiovascular risk profile that includes more factors than cholesterol and triglycerides. Triglycerides and cholesterol are transported in blood in association with lipoproteins, that can be separated by ultracentrifugation into four main classes according to their density: chylomicrons, very low-density lipoproteins (VLDL), low-density-lipoproteins (LDL), and high-density lipoproteins (HDL). The current lipid profile measured focuses on the lipid components of lipoproteins. Because proteins associated with lipoproteins, apoproteins, play a central role in lipid homeostasis, important research efforts have been directed to the study of apoproteins.

Free-flow isotachopheresis (ITP) and capillary ITP (cITP) has been utilized for many years to study plasma lipoproteins. The discriminating principle is based on the net charge of lipoproteins. cITP is a high-resolution electrophoretic technique, by which ionic sample components are separated according to their net electric charge and without molecular sieve effects. With cITP, lipoprotein analysis can be performed directly from whole serum and offers the potential of a reliable and automated quantitation of lipoprotein subpopulations. Sample pretreatment is negligible and only few nanolitres of sample are necessary for the analysis. LDL are a heterogeneous population of particles that varies in size, density, composition, and electric charge. One significant aspect of this variability, relevant to atherosclerosis, is the phenotypic pattern of LDL density and size distribution among individuals with and without coronary artery disease. Using nondenaturing gradient gel electrophoresis, various LDL subgroups have been identified on the basis of size. Individuals with lipoprotein profiles enriched in small dense LDL were found to be predisposed to coronary artery disease. Higher plasma levels of LDL have been found in patients

with acute myocardial infarction, unstable angina, and thrombogenic carotid atherosclerosis. The method of study of LDL, which uses ion exchange chromatography of LDL isolated by ultracentrifugation, requires particular care to avoid artefacts due to *in vitro* auto-oxidation of the LDL and is time consuming. HDL are a family of protein–lipid complexes that play a central role in cholesterol transport. HDL collectively contain apolipoproteins (apo) A-I and A-II as major protein components, together with apoC, E, and A-IV. Changes in HDL composition occur during normal metabolism, as the result of a particular genetic profile, or as a consequence of disease. The protein composition of lipoproteins can be analysed by chromatography, electrophoresis, or immunoassay. SDS-PAGE resolves proteins according to molecular size, while charge separation can be achieved by zone electrophoresis or isoelectric focusing. Quantification of protein bands after electrophoresis is achieved by immunoblotting or by staining with Coomassie Blue. However, due to differences in the chromogenicity of different apolipoproteins, these staining methods are only semiquantitative. Immunoassays offer good sensitivity and precision, but results can vary with different antisera. Furthermore, immunoassays do not distinguish between different apo isoforms. The availability of high performance capillary electrophoresis systems has created the possibility of applying this technology to lipoprotein analysis. Protein separation is performed at high field strengths in micropore capillaries, with direct monitoring by online UV detection. The separation is analogous to that achieved with slab gel systems, except that no support media are used, electrophoresis being carried out in a free solution, and results are obtained in minutes rather than hours. Separations based on differences in molecular size are performed in a SDS-containing UV transparent polymer network. This mode, usually termed ‘capillary SDS gel electrophoresis’ (though it actually uses a non-gel matrix), has been found to give similar results to those obtained with SDS slab gel electrophoresis.

Determination of Serum Protein Phenotypes and Microheterogeneities

The determination of the phenotype of particular serum proteins may have clinical relevance. Hereditary deficiencies of the proteinase inhibitor α_1 -antitrypsin, one of the most common inborn metabolic errors in Europeans, lead to pulmonary emphysema in young adults and to liver cirrhosis in children. Many distinct subtypes have been identified using isoelectric focusing, the most common normal phenotype being MM, whereas the major deficient

phenotypes are termed MS, MZ, SS, SZ and ZZ. The last form, ZZ, is associated with low concentration of the protein in plasma and with severe clinical manifestations. Isoelectric focusing in immobilized pH gradients represents a major improvement, and the method can be utilized for subtyping many different proteins with high reproducibility.

The microheterogeneity of serum glycoproteins in patients with chronic alcohol abuse as well as in patients with carbohydrate-deficient glycoprotein syndrome can be globally studied by two-dimensional electrophoresis, whereas SDS-PAGE and Western blotting allows detailed comparison and characterization of specific proteins.

Diagnosis of Haemoglobinopathies and Haemoglobin A1c

Disorders of haemoglobin synthesis such as sickle cell disease, β - and α -thalassaemias or haemoglobin variants – grouped under the term ‘haemoglobinopathies’ – are frequently observed, and up to 45% of the newborns from regions at risk present an abnormal haemoglobin. Therefore, it is of importance to have cost-effective methods to screen large populations. Isoelectric focusing has been used for many years, and when performed correctly, produces excellent haemoglobin separation, with very little band overlap when bands are measured to 0.1 mm against controls. It has been shown that high-power liquid chromatography also allows accurate diagnosis of the haemoglobinopathies, and that both approaches can be used for a universal screening. Another interesting approach to study haemoglobin variants is capillary isoelectric focusing. The technique allows high-efficiency separation and precise quantitation of haemoglobin variants over a wide range of concentrations.

Haemoglobin A1c (Hb A1c) is the analyte of choice for monitoring metabolic control in patient with diabetes mellitus. Hb A1c can be measured using capillary electrophoresis, without apparent interference by other haemoglobin variants such as Hb F, Hb S or Hb C.

Genotyping of Proteins

Many complex biological questions, encountered in all fields of medicine, have been solved using DNA-based technologies. It is now possible to make many different prenatal diagnoses using genetic testing with one technique or a combination of the three basic molecular testing techniques – nucleotide sequencing, restriction fragment length polymorphism mapping and molecular DNA analysis using the polymerase chain reaction (PCR) – routinely used to assess gene

mutations. Apolipoprotein E (apoE) is a secreted glycoprotein with a molecular mass of 35 kDa which is synthesized primarily in the liver and brain. ApoE plays a critical role in lipid metabolism through its function of redistributing lipids amongst the cells of various organs. It is a constituent of VLDL and of a subclass of HDL. The *APOE* gene is polymorphic and its three common alleles ϵ 2, ϵ 3, and ϵ 4 code for isoforms E2, E3 and E4, respectively. The isoforms E3 and E4 differ from E2 by single arginine (R) substitution at one or both cysteine (C) at position 130 and 176 of the apoE amino acid sequence (accession number P02649; SwissProt database). Compared with allele ϵ 3, reduced LDL cholesterol (LDL-c) and apoB levels frequently accompany the ϵ 2 allele, higher LDL-c levels occurring with the ϵ 4 allele, and both ϵ 2 and ϵ 4 alleles are associated with hypertriglyceridaemia. In addition to the dyslipidaemic tendency, the relative odds for prevalent coronary heart disease are found to be increased with the ϵ 4 allele. A compelling association between risk of Alzheimer’s disease in both late-onset familial Alzheimer’s disease and sporadic Alzheimer’s disease with the ϵ 4 allele has been also demonstrated. *APOE* genotyping is usually determined by a blood test using DNA isolated from leukocytes, embedded tissues, Guthrie spots, buccal epithelial cells and restriction isotyping. The method is based on the existence of a GCGC recognition site for the endonuclease *HhaI* overlapping the coding sequences present for amino acids 130 and 170 in the ϵ 4 allele, absent in position 130 in the ϵ 3 allele, and absent in both position 130 and 170 in the ϵ 2 allele. A 244-bp sequence including the two polymorphic sites is amplified by using PCR and is digested by *HhaI* (Figure 1). The resulting fragments are separated by electrophoresis on polyacrylamide gels. After electrophoresis, the gels are either treated with ethidium bromide or are silver stained. The method cannot detect rare *APOE* variants unless nucleotide substitution alter the *HhaI*-restriction sites within the PCR-amplified region. In that case the rare variants are identified only by using DNA sequencing. PCR and restriction isotyping for *APOE* genotyping must be preferred to isoelectric focusing (IEF). Because the post-translational modifications of apoE such as glycosylation or desialylation alter the electric charges of the isoforms, misclassification of genotypes currently occurs when using IEF.

Small Molecules (Drugs, Steroids) Monitoring

Drugs, licit or illicit, play a pivotal role in almost all aspects of life. Monitoring of drugs is of major importance for regulatory authorities, in clinical

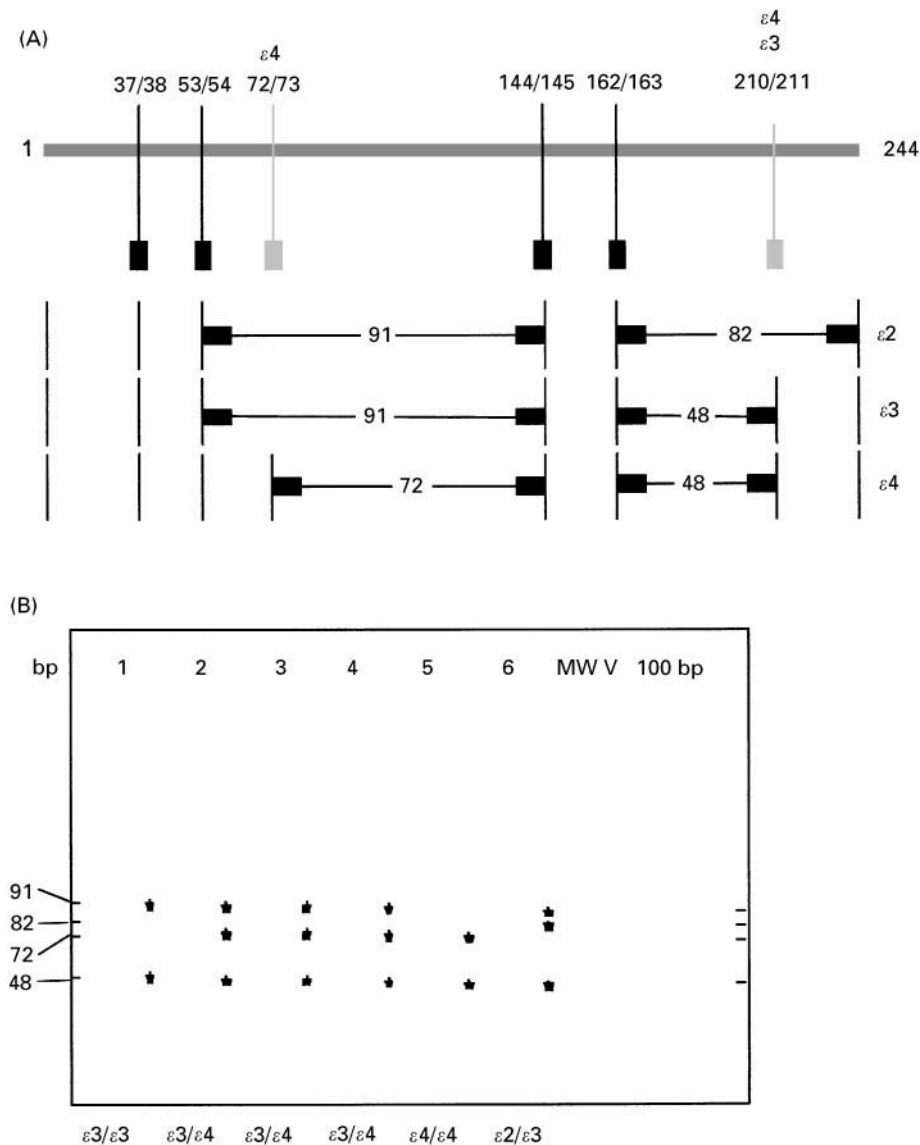

Figure 1 Application of PCR to the analysis of apolipoprotein E. (A) Map of the PCR-amplified region encoding common *APOE* isoforms and location of *HhaI* cleavage sites. (B) Silver-stained PAGE after the electrophoretic separation of *HhaI* fragments from different patients.

settings, in forensic science, for drug testing at the workplace, and in the pharmaceutical industry. With the advent of fused-silica capillary instrumentation, drug analysis by capillary electrophoresis has made important progress. Capillary electrophoresis of drugs, as well as their metabolites in almost all biological samples, has been shown to provide high-quality data that can be used for diagnostic drug monitoring. Corticosteroid hormones are usually analysed by immunological techniques or HPLC. Immunoassays are prone to interference from various compounds, a disadvantage not observed with HPLC. However, the latter technique is hampered by the large sample and eluent volumes needed. Corticosteroid hormones such as cortisone, cortisol, progesterone and oestro-

gen can be studied using mixed micellar electrokinetic capillary chromatography (MEKC), using borate buffer and SDS. The separation is rapid and quantitation is efficient.

Cerebrospinal Fluid Analysis

Analysis of cerebrospinal fluid (CSF) proteins using electrophoretic techniques is particularly useful in the diagnosis and management of neurological diseases particularly in the detection of immune response within the central nervous system (CNS). In healthy individuals, all CSF immunoglobulins are derived from plasma. However, in most of the inflammatory conditions within the CNS, activated B-lymphocytes

secrete their immunoglobulins directly into the brain extracellular space. This local immune response occurs typically in demyelinating disorders such as multiple sclerosis, in chronic CNS infections as well as in autoimmune disorders with neurological involvement. An intrathecal synthesis of immunoglobulins can be detected either by quantitative methods and the results are expressed using various indexes or by qualitative methods such as IEF and Western blotting. Because the locally synthesized immunoglobulins are the product of a limited number of clones, they currently produce an oligoclonal pattern superposed to the plasma pattern (Figure 2). IEF is now considered as a more sensitive test than the quantitative index for the detection of an intrathecal immune response. The diagnostic sensitivity and specificity of both quantitative and qualitative tests has

been evaluated in samples from 1007 patients with neurological diseases. It was found that IEF has a sensitivity of 95% for multiple sclerosis against 67% for the quantitative tests and a specificity with a false-positive rate of 0% versus 3.5% for the quantitative tests.

The diagnosis and the treatment of the discharge of CSF (liquorrhea) from the subarachnoid space into the nasal or aural mucosa (CSF rhinorrhea and otorrhea) is a critical clinical problem. The most common cause of liquorrhea is traumatic fracture; in a large series of pediatric patients with temporal bone fractures, liquorrhea was noted in 25% of the patients. Other causes are neurosurgical procedures, intra- and extracranial tumours, as well as primary CSF rhinorrhea through congenital bony dehiscences. The diagnosis of liquorrhea is important in view of developing a potentially fatal meningitis. The use of prophylactic antibiotics does not appear to be beneficial in reducing the incidence of post-traumatic meningitis. Surgical intervention is therefore necessary. Detection of β_2 -transferrin is now considered as the most reliable test in the identification of CSF rhinorrhea and otorrhea. β_2 -transferrin is a transferrin isoform which is locally synthesized in the central nervous system. This isoform is characterized by the presence of truncated N-glycans devoid of terminal galactose and sialic acid. The serum transferrin and β_2 -transferrin isoforms found in CSF are separated by native electrophoresis using agarose and detected by immunoblotting. Because there is no gold standard for the diagnosis of liquorrhea, the sensitivity and the specificity of the test are unknown.

Urine Analysis

Electrophoretic methods have been widely used for the clinical analysis of the proteins contained in urine (proteinuria). Normally, the renal glomeruli restrict filtration of plasma proteins, and only traces are present in the urine. In several renal diseases and particularly in patients with glomerulonephritis, nephrosis, glomerulosclerosis and IgA nephropathy, large amounts of proteins may be present in the urine. This is the reason why so many different electrophoretic techniques, including SDS-PAGE, isoelectric focusing, and high-resolution two-dimensional polyacrylamide gel electrophoresis have been applied over the years to study in detail the protein composition of the urine of patients with kidney diseases.

The Diagnosis of Infectious Diseases by Western Blotting

Despite the analytical power of gel electrophoresis, direct specific identification of separated components

Figure 2 Analysis of the immunoglobulins of the cerebrospinal fluid. Typical IgG patterns of sera (S) and of cerebrospinal fluid (CSF) separated by isoelectric focusing and revealed by Western blot. (A) Normal control. (B) Patient with multiple sclerosis. The arrow heads indicate the oligoclonal bands found only in the CSF.

by ligands such as antibodies, lectin or enzymes was generally hindered by the pore size of the gel matrix. Thus the development of protein blotting techniques that enabled the separate components to be transferred from gels onto membranes where they were bound and available for participation in a range of reactions was of enormous practical significance. Basically, with these techniques, viral proteins, either from culture fluid or obtained by recombinant molecular technologies, are separated by SDS-PAGE, then blotted from the polyacrylamide gel matrix onto membranes by an electrophoretic transfer, and finally identified using enzyme immunoassay. The Western blot method has been used in key epidemiological studies that reported the unambiguous association of human immunodeficiency virus (HIV) with AIDS, and is still an essential tool for confirming the presence of antibodies to HIV. Western blot has been used as the 'gold standard' confirmatory test for specimens found to be reactive in screening assays. Protein blotting can be applied to a large variety of infectious diseases, to study allergens in patients with allergy as well as to identify autoantigens in patients suffering from autoimmune disorders.

The transmissible spongiform encephalopathies or prion diseases constitute a group of progressive and fatal neurodegenerative diseases that affect both human and animals. The diseases affecting humans include Creutzfeldt-Jakob disease (CJD) for which three main forms have been recognized: inherited, sporadic, and acquired (iatrogenic). Patients with CJD present a progressive dementia with myoclonus usually associated with the presence of sharp-wave complexes on their electroencephalogram. The gold standard for a definitive diagnosis of CJD require a histological examination of the brain and immunostaining for the protease-resistant prion protein (PrP^{res}). Several CSF proteins such as neurone-specific enolase, S-100b, CK-BB, ubiquitin and protein 14-3-3 have been proposed as potential pre-mortem markers for CJD. Amongst them, only protein 14-3-3 proved useful diagnostically. The differential expression of CSF proteins in patients with CJD has been evaluated by using two-dimensional electrophoresis, and two protein spots with CJD has been evaluated by using two-dimensional electrophoresis, and two protein spots (proteins 130 and 131) were identified. N-terminal sequencing of protein 130 matches the sequence of 14-3-3 β , a brain-specific protein of 28 kDa which is believed to have a regulatory function in monoamine biosynthesis. A Western blot assay has been developed, using a commercially available antibody directed against 14-3-3 β (Santa Cruz Biotechnology) which cross-reacts with protein 130 and 131 (Figure 3). It was

found that the 14-3-3 immunoassay had an overall sensitivity of 96% (68 true-positive results and 3 false-negative results) and an overall specificity of 88% (164 true-negative and 22 false-positive results). Interestingly, the specificity of the immunoassay amongst all patients with dementia was 96% (90 true-negative and 4 false-positive results). It was also observed that the immunoassay may become positive early in the course of CJD. However the immunoassay does not allow a quantitation of the 14-3-3 proteins and needs further validation with larger numbers of patients.

Identification of Microorganisms

Pulsed-field gel electrophoresis (PFGE) is a method widely used to separate fragments of DNA as long as several million bases by subjecting the gel to an electrical current alternately delivered from two angles in timed intervals, which minimizes diffusion of large molecules. PFGE has many important clinical applications, particularly in the field of infectious diseases. PFGE allows typing bacteria such as group A streptococci, *Staphylococcus aureus*, *Escherichia coli* or *Salmonella enterica*. PFGE can be particularly useful for assisting epidemiological investigations of illnesses caused by a common-source of pathogen such as *Escherichia coli* O157:H7 in food poisoning or to demonstrate that recurrent episodes of staphylococcal bacteraemia are primarily related to relapses rather than to new infections. The technique is commonly known as DNA fingerprinting.

Figure 3 Application of Western blot to the diagnosis of Creutzfeldt-Jakob disease. Immunoblot by using anti-14-3-3 β after SDS-PAGE separation of (A) human brain proteins, (B) cerebrospinal fluid proteins from a patient with Creutzfeldt-Jakob disease and (C) normal control cerebrospinal fluid. Note that anti-14-3-3 β immunoglobulins bound nonspecifically to a cerebrospinal fluid protein with a molecular mass close to 55 kDa.

Summary

Electrophoretic techniques will certainly continue to be applied in the clinical laboratory for many years to come. However, only highly reproducible methods such as those based on capillary electrophoresis will survive on the condition that they can be applied to resolve heterogeneous clinical problems and that they can be fully automated with electronic handling of the data. The evolution of electrophoretic techniques achieved over the last few years has allowed a revolution in medical science. However, in terms of manual operations, the good old time of 'blue fingers' has probably finished.

Introduction

The separation of polypeptides by electrophoresis allowed Arne Tiselius to describe protein fractions corresponding to albumin, α -, β -, and γ -globulins in serum with the first published diagram of human serum protein electrophoresis in 1939. The number of fractions slowly expanded into electrophoretic subfractions identified as α_1 , α_2 , β_1 , β_2 , γ_1 and γ_2 . The mobility characteristics of these fractions are still used to denote serum proteins such as α_1 -macroglobulin, α_2 -antiplasmin or β_2 -microglobulin. Sophisticated new electrophoretic techniques for identifying many proteins simultaneously and relating them to diseases have been developed over the years, many of them being described in other studies. Almost all body fluids have been studied by electrophoresis, serum, urine and cerebrospinal fluid being evaluated in great detail by different techniques. However, despite the major developments and progress achieved in protein separation, only a restricted number of methods are routinely used in the clinical laboratory. Nowadays, serum protein electrophoresis is mainly used to study major serum protein alterations such as those observed in patients with inflammatory, liver or kidney diseases, as well as in patients presenting lymphoproliferative disorders and alterations of immunoglobulin (Ig) production. Electrophoretic techniques, in association with ultracentrifugation, are also used to study lipoproteins and to classify hyperlipidaemic disorders.

Here, we provide selected clinical situations studied by electrophoretic methods, with a particular emphasis on 2D-PAGE, in order to illustrate how electrophoresis can be used to gain insight into particular clinical problems.

Monoclonal Immunoglobulins

The large diversity of antibodies in an individual results from highly complex mechanisms influencing B-cell development, expansion, and immunoglobulin (Ig) secretion. This diversity is so complex that elec-

trophoretic techniques applied to sera from healthy adults cannot separate individual clonal products. Immunoglobulin produced by an expanding B cell clone to a level permitting detection by electrophoretic techniques is known as 'monoclonal gammopathy' (MG), and has been observed in a wide variety of disease. MG can be also observed in humans without overt disease and is termed 'benign MG', or 'monoclonal gammopathy of undetermined significance'. The frequency of benign MG has been increasing in parallel with the refinement of the techniques. Identification of monoclonal immunoglobulins requires sensitive and rapid screening methods. Electrophoresis on cellulose acetate membrane is satisfactory for initial screening.

High-resolution agarose gel electrophoresis (HRE) is more sensitive for the detection of rare monoclonal proteins (**Figure 1**). Confirmation of the presence of an MG should be performed using methods such as immunoelectrophoresis (IEP) or immunofixation electrophoresis (IFE). IEP was described in 1953, and, until recently, was considered as the method of reference. As a routine procedure, it is time-consuming, and requires a high level of technical expertise. The consequence of the long diffusion process is that small amounts of protein become too dilute to be detected, resulting in low sensitivity. The most important drawback of IEP is the so-called 'umbrella effect'. Furthermore, the demonstration of κ and λ monoclonal light chains belonging to IgA or IgM isotypes is often masked by the presence of polyclonal IgG, that, because of faster diffusion, migrates ahead to an area situated between IgA and IgM. IFE, like IEP, includes two steps, but without the diffusion process. In the first step, protein fractions are separated by agarose gel electrophoresis; in the second step, they are revealed by overlaying of antiserum specific to the different immunoglobulin heavy and light chains. The technique is considered as the procedure of choice in the routine diagnosis of MG, because of its simplicity, speed, and sensitivity. Other advantages of the method are ease of interpretation and the absence of diffusion. Furthermore, the enhanced sensitivity of IFE also yields more frequent detection of low concentration MG and, what is more important, of multiple immunoglobulin bands or subtle bands of restricted heterogeneity. In such cases, further assessment of the clonality of immunoglobulins depends on additional techniques such as immunoblotting, immuno-isoelectric focusing or high-resolution two-dimensional polyacrylamide gel

Figure 1 High resolution serum protein agarose electrophoresis profiles. Serum protein electrophoresis, and protein densitometry of serum samples from patients presenting monoclonal IgG- λ , IgM- λ and IgA- λ gammopathies were performed by using commercially available kits. The isotype of the monoclonal heavy chains as well as the type of the monoclonal light chains were identified using immunofixation electrophoresis. The protein peaks corresponding to the monoclonal components are shown by arrowheads.

electrophoresis (2D-PAGE). With 2D-PAGE, α , μ , γ and δ chains appear in nonoverlapping regions of protein maps (Figure 2). Monoclonal heavy chains are easily differentiated from polyclonal heavy chains, according to their different two-dimensional electrophoretic patterns. Polyclonal heavy chains are highly heterogeneous and are resolved as 'unspotted' diffuse zones whereas monoclonal heavy chains show charge and, to a lesser degree, size microheterogeneity.

Polyclonal light chains appear as clustered nondiscrete spots following 2D-PAGE, and form cloudy zones with unevenly distributed densities. In about two-thirds of patients with MG, monoclonal light chains are detected as a dominant and well-defined spot. In the remaining one-third of the patients, examined monoclonal light chains disseminate in more than one spot. In patients with monoclonal heavy chain disease, only fragments of monoclonal heavy chains are synthesized and released into the circulation by malignant lymphoplasmocytic cells. Such fragments are identified with immunofixation electrophoresis as proteins bands that only bind specific anti-heavy chain antibodies, but not specific anti- κ or anti- λ light chain antibodies (Figure 3).

However, the abnormal characteristics of such monoclonal heavy chains are best studied using 2D-PAGE of protein-G purified fractions, as demonstrated in Figure 4. A set of spots (γ') is observed at the basic side of the gel, in an area corresponding to pI from 5.8 to 6.8, and M_r of 32 to 38 kDa. Spots corresponding to polyclonal IgG γ chains and polyclonal immunoglobulin light κ and λ chains are also identified. No spot corresponding to a monoclonal immunoglobulin light chain is observed. The 32 to 38 kDa M_r of the monoclonal γ' chain indicates that it is a fragment of a normal γ chain, and the microheterogeneities of the pI suggest that it is glycosylated. Finally, the binding of the molecule to protein G implies that the Fc region of the immunoglobulin is intact. In contrast to what was seen in the serum of another patient presenting the same disease, abnormal monoclonal γ chains of higher M_r are not observed.

Cold Agglutinins and Cryoglobulins

Cold agglutinins (CAs) are immunoglobulins, most frequently IgM, that agglutinate erythrocytes at temperatures below 37°C. Immunohaemolytic anaemia related to CAs can be observed in a wide variety of diseases (Figure 5).

Monoclonal CAs, generally belonging to the IgM isotype, are observed in patients with lymphopro-

Figure 2 High-resolution two-dimensional polyacrylamide gel electrophoresis in a case of monoclonal IgD- λ . (A) Serum and (B) purified IgD (anti- λ Sepharose). a, albumin; μ , polyclonal heavy chains of IgM; α , polyclonal heavy chains of IgA; γ , polyclonal heavy chains of IgG; κ, λ , polyclonal immunoglobulin light chains; δ' , monoclonal δ -chain monoclonal; λ' , monoclonal λ chain; t, transferrin. The gels were silver stained, and presented with the higher molecular weights at the top, and the acidic side on the left. (Reproduced from Tissot JD, Schneider P, Hohlfield P *et al.* (1993) Two-dimensional electrophoresis as an aid in the analysis of the clonality of immunoglobulins. *Electrophoresis* 14: 1366, with permission from Wiley-VCH, Weinheim.)

liferative disorders or suffering from the 'idiopathic' chronic cold agglutinin disease, whereas polyclonal CAs, also belonging to the IgM isotype, may be found in patients with various infectious diseases, but more particularly in patients with Epstein-Barr virus or *Mycoplasma pneumoniae* infection. The evaluation of the clonality of CAs, that are frequently at very low

concentrations in serum, can be easily performed using 2D-PAGE. CAs are isolated from serum by cold absorption of immunoglobulins on red blood cells. After several cold washes, red blood cells coated with CAs are rewarmed to 37°C. After centrifugation, the supernatant is collected and studied with 2D-PAGE. As mentioned in the previous section, polyclonal IgM are quite easily differentiated from monoclonal IgM according to their different electrophoretic patterns (Figure 6).

Cryoproteins are defined as proteins precipitating at low temperature. Most frequently, the precipitate contains immunoglobulins, and are therefore called cryoglobulins. Three types of cryoglobulins have been described: type I contains a single monoclonal immunoglobulin, whereas type II is a mixture of a monoclonal immunoglobulin with polyclonal immunoglobulins, and type III is a mixture of polyclonal immunoglobulins of different isotypes, most frequently IgG and IgM (Figure 7). Type II and type III are also called mixed cryoglobulins. A new type II-III class of cryoglobulins, containing polyclonal IgG associated with a mixture of polyclonal and monoclonal IgM has been recently described through 2D-PAGE. In a series of 265 cryoglobulins studied with 2D-PAGE, we identified type I, II, II-III, and III in 3.4%, 26, 22.6 and 43.8% of the cases, respectively.

Figure 3 Immunofixation electrophoresis in a case of γ -chain disease. A serum sample from a 56-year-old patient was analysed by immunofixation electrophoresis. A protein band (arrowheads) was shown to react with anti-human immunoglobulin chain antiserum, but not with anti-human κ or λ light-chain antibodies. SPE, serum, protein electrophoresis; G, A, M, κ , λ , immunodetection of protein bands with corresponding antisera.

Figure 4 High resolution two-dimensional polyacrylamide gel electrophoresis in a case of γ -chain disease. Protein G purified protein fraction from a 56-year-old patients presenting γ -chain disease was analysed using 2D-PAGE. γ , polyclonal heavy chains of IgG; γ' , spots corresponding to monoclonal γ chain fragments; κ - λ , polyclonal immunoglobulin light chains. The gel was silver stained, and presented with the higher molecular weights at the top, and the acidic side on the left.

They were composed of oligoclonal immunoglobulins mixed with traces of polyclonal IgG in 4.2% of the cryoglobulins studied. These cryoproteins were tentatively named type II-III_{variant} cryoglobulins.

Fetal Proteins

Gene expression and regulation are dependent on highly sophisticated mechanisms. The genome-related modifications of protein synthesis and expression are most evident during fetal development.

The development of a safe and easy technique for fetal blood sampling has greatly improved our know-

ledge of normal fetal physiology, including some aspects of protein biology. However, the amount of pure fetal blood which can be derived for research purposes from samples obtained for prenatal diagnosis is obviously limited. Thus, electrophoretic techniques that allow studies of plasma and serum proteins contained in minute samples (usually less than 1 μ L) must be applied. Many proteins detected in the plasma and serum of adults are already present in the blood of normal embryos at a very early stage of gestation. Not all proteins are produced by the conceptus but many are the result of transfer from the mother across the placenta. Some proteins remain at a fraction of their adult levels throughout intrauterine life, others are progressively produced in increasing amounts when term approaches, and finally, others are present in higher concentrations during fetal life than after delivery. Modifications of plasma and serum protein concentrations during early extrauterine life have been well documented. The plasma concentration of a given protein is governed not only by fetal synthesis and degradation, but also by the result of the exchange between mother and fetus through the placenta. Materno-fetal transfer of proteins involves several different mechanisms such as a first-order process or active transport. The concentration of each fetal plasma protein results of a balance between opposing dynamic metabolic and physiological processes which proceed simultaneously. The relative impact of these factors contributing to a plasma protein concentration continuously shifts during development, and not always in the same manner. 2D-PAGE is an ideal tool to study such a dynamic process. Fetal protein maps reveal spots which are always absent in those of adults. A readily evident set of spots, located at the acid side of albumin is found in such fetal samples and corresponds to α -fetoprotein (Figure 8). This protein is less apparent as gestational age increases. A second 'fetal' polypeptide, characterized by an apparent M_r of 46 kD and a pI of 5.0 is observed as a small spot, located under those of α_1 -antitrypsin. N-terminal microsequencing (25-EDPQ) and immunoblotting using specific anti- α_1 -antitrypsin antibodies reveal that this spot most likely

Figure 5 Classification of cold agglutinins.

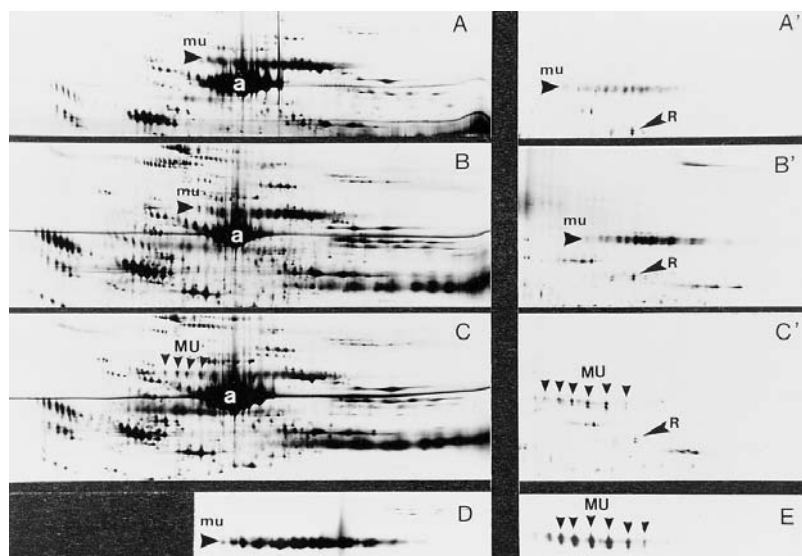

Figure 6 Characterization of cold agglutinins using high resolution two-dimensional polyacrylamide gel electrophoresis. Details of electrophoretograms of plasma/serum samples (A–C) and their purified cold agglutinins fractions (A'–C'). Purified polyclonal (D) and monoclonal (E) IgM heavy chains are shown as controls. corresponds to a fetal-specific form of α_1 -antitrypsin, already identified in mouse plasma. This polypeptide is observed in all fetal samples and in all samples obtained from infants of under two years of age but is either undetectable or appears as a shaded spot in adults.

Genetic polymorphism of some serum proteins such as Gc-globulin, Apo A-IV, or Apo E (Figure 9) can be also studied using 2D-PAGE. As shown in Table 1, the technique allows determination of the frequency of the Apo-E phenotypes, as well as the calculation of the gene frequencies.

During fetal development, 2D-PAGE reveals a progressively more and more complex protein pattern and an increase in the size of many spots. Three major protein pattern modifications are observed on 2D gels of fetuses at different gestational ages: (a) the progressive appearance of the protease inhibitor α_1 -antichymotrypsin; (b) the progressive increase of polyclonal IgG, which is particularly evident during the last weeks of pregnancy; (c) the gradual diminution of α -fetoprotein which is undetectable on protein maps of term newborns. On the other hand, before the 38th week of gestation, polyclonal IgA or IgM heavy chains, as well as the two main proteins involved in free haemoglobin transport and catabolism — haptoglobin and hemopexin — are not detectable.

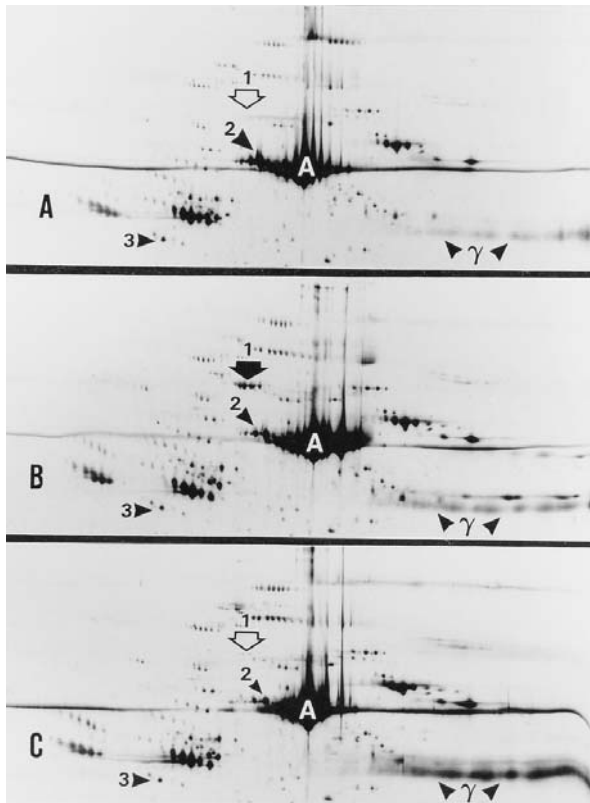

Figure 8 Fetal proteins. Details of electrophoretograms of plasma samples obtained from fetuses at 22 (A), 28 (B), and 32 weeks (C) of gestation. A, albumin; γ , immunoglobulin gamma chains; 1, dimers of fibrin (γ chains), only observed when small clots were present in the sample; 2, α -fetoprotein; 3, fetal form of α_1 -antitrypsin. The gel was silver stained, and presented with the higher molecular weights at the top, and the acidic side on the left.

Carbohydrate-deficient Glycoprotein Syndrome (CGDS)

Carbohydrate-deficient glycoprotein syndrome (CDGS) is a group of autosomal recessive disorders affecting multiple organ systems. All of the affected patients present moderate or severe brain disorders. In the first years of life, CDGS is characterized by hypotonia with failure to thrive, dysmorphism and coagulation abnormalities. These clinical manifestations are the direct embryologic and physiological consequences of an underglycosylation of protein. The alterations are related to a reduced number of entire *N*-glycans on glycoproteins and they have been described for serum transferrin, α_1 -antitrypsin, α_1 -acid glycoprotein, α_1 -antichymotrypsin, fetuin, ceruloplasmin and antithrombin III, C3a and C4a. In patients with CDGS type 1a and type 1b, the post-translational defect is due either to a deficiency of phosphomannomutase or a deficiency of phos-

Figure 9 Genetic polymorphism of apolipoprotein E in fetuses. Phenotype E3/4 (A, fetus at the age of 22 weeks, A' fetus at the age of 30 weeks), phenotype E2/3 (B, fetus at the age of 22 weeks, B' fetus at the age of 30 weeks), phenotype E3/3 (C, fetus at the age of 22 weeks). M, α_1 -microglobulin; C, γ chain of complement factor C4; A-I, apolipoprotein A-I, A'-I, pre-apolipoprotein A-I; κ and λ , immunoglobulin light chains. The gel were silver stained, and presented with the higher weights at the top, and the acidic side on the left.

phomannose isomerase. Both these defects alter the metabolism of mannose in cells and result in a decrease of GDP-mannose for *N*-glycan synthesis. The diagnosis is usually made by isoelectric focusing of serum transferrin showing a different pattern of cathodal shift due to the loss of terminal sialic acids. Another way of diagnosis is to separate the transferrin isoforms lacking their *N*-glycans by using SDS-PAGE. Other more complex diagnostic methods have been

reported such as 2D-PAGE and matrix-assisted laser desorption ionization–time of flight (MALDI–TOF) mass spectrometry of serum transferrin.

We have described the characterization of a new antibody which is specifically directed against the *N*-glycan binding site localized on the asparagine-432 of transferrin and which allows immunodetection of transferrin devoid of *N*-glycan (Figure 10). This antibody has the potential to provide a new immunochemical tool for the CDGS diagnostic.

Conclusion

Numerous diseases can be diagnosed using electrophoretic analyses of body fluid proteins. However, many different electrophoretic techniques are available. Electrophoresis on cellulose acetate is employed to study many different enzymes such as serum amylase, pancreatic isolipase, and pyruvate kinase. Agarose gel electrophoresis is extensively used to gain insight into the understanding of lipoprotein biology. Isotachopheresis or ‘displacement’ electrophoresis allows the simultaneous concentration and effective separation of different charged substances, including biological macromolecules. Affinity electrophoresis is used to evaluate cross-reactivity of antihapten antibodies whereas lectin affinity electrophoresis is best used to characterize serum glycoproteins. Capillary electrophoresis offers the possibility of rapid and automated analysis of different kinds of molecules, with high reproducibility and improved quantification. Isoelectric focusing as well as SDS-PAGE are cornerstone techniques used to characterize polypeptides.

2D-PAGE is increasingly used as an important tool for biological research. However, despite the fact that these techniques are particularly useful for studying a clinical problem, routine clinical analysis is frequently incompatible with the use of such sophisticated techniques. As illustrated by several examples presented in this article, 2D-PAGE can be chosen as a complementary technique to gain insight into several specific clinical problems. The combination of different electrophoretic techniques can be very useful to resolve complex problems.

Introduction

Clinical medicine is mainly based on the results of chemical analysis and these results are very important. It is estimated that more than 50% of diagnoses are based on laboratory data. The analyses are usually done using immunoassays, chromatographic and spectroscopic methods. The combined techniques, e.g. liquid chromatography–mass spectrometry (LC/MS) gas chromatography–tandem mass spectrometry (GC-MS-MS) are also applied. The development of sophisticated methods of analyses reduced interest in simple and rapid methods such as thin-layer chromatography (TLC). Starting from paper chromatography and improved over the years, TLC has become very useful also for clinical medicine. TLC has been used to solve analytical, and sometimes preparative, problems.

A large number of publications on the use of TLC for clinical medicine analysis can be found in the literature. An excellent compilation concerning different applications of analytical methods (including TLC) for isolation and identification of drugs in pharmaceutical, body fluids and post-mortem materials is the book edited by Moffat. This work, prepared in the Department of Pharmaceutical Sciences of the Pharmaceutical Society of Great Britain, is a comprehensive and clear account of clinical analytical chemistry up to 1986. An excellent supplement, covering the early 1990s, is the monograph of Jain. More recent works more commonly refer to applications of instrumental TLC.

General Principles of Clinical Medicine Analyses by TLC

TLC is a most economical and cost-effective technique and ideally suited for performing clinical analyses of biological samples, where the sample load is high. The method is characterized by high selectivity, enabling separation of the analyte from interfering substances. At least two basic groups of applications of TLC in clinical medicine analysis can be distinguished. The most important of them are where TLC has been applied for analytical and screening purposes where qualitative or semi-quantitative results are required. The second group concerns work, where TLC performs the function of a clean-up technique for initial sample preparation.

Clinical analysis presents a difficult analytical problem. The proteins, lipids, or carbohydrates, usually present in biological samples, may interfere with analytes. Analyses are also made difficult by the fact that many substances of interest are only slightly soluble in organic solvents.

Sample Preparation

There is a generally accepted view in laboratory practice, that the TLC stage of sample preparation is of little importance because it is merely a clean-up technique. This is incorrect, especially in the case of clinical medicine analysis where analytes are to be found in complex matrices such as plasma, serum or urine, whole blood, faeces, saliva, cerebrospinal fluid, gastric fluid or body tissues. These matrices are very complex multicomponent mixtures and therefore sample preparation prior to analysis cannot be omitted.

The process of separation from biological samples and purification of analytes is usually realized by protein precipitation, dialysis, hydrolysis, ultrafiltration, dilution, liquid–liquid or solid-phase extraction. Originally, the most common extraction method was

liquid-liquid extraction but in recent years solid-phase extraction has become an increasingly popular method for isolation of compounds from biological matrices. Lyophilization, saponification, microwave processing and supercritical fluid extraction are used less commonly.

Chromatogram Development Techniques

Chromatographic separation of clinical samples is carried out mainly in normal phase systems. High performance silica gel, aluminium oxide, polyamide and amino-bonded silica gel are commonly used as stationary phases for the separation of basic and acidic drugs and other polar substances such as amino acids. It is better to separate neutral drugs and other nonpolar compounds in reversed-phase (RP) systems. The commonest stationary phases for RP systems are silica gel with chemically bonded octyl and octadecyl groups. Numerous solvent systems consisting of mixtures of organic solvents such as hexane, methanol, chloroform, ethyl acetate or mixtures of polar solvents with water, organic acids or ammonia have been used. It is sometimes advantageous to introduce modifying agents to the mobile phase to improve selectivity.

One-dimensional ascending or horizontal techniques have usually been applied for the development of chromatograms in a closed chamber. For clinical medicine needs, there are standard TLC kits (Toxi-Prep type and Toxi-Lab). These are commercially available and have been used above all for extraction, concentration and analysis of the acidic, basic, and neutral drugs. Recently, multiple gradient development (AMD), two-dimensional techniques and over-pressure layer chromatography have been more often applied to the analyses listed in Table 1.

Visualization and Quantification

Identification of analytes is achieved by co-chromatography of reference standards with the unknown and comparison of R_F values. TLC retention indices are less reliable than for other chromatographic methods so that additional information from individual spots is needed. Post-chromatographic derivatization is the basic method of visualization especially when there exists a specific reaction that can confirm the presence of particular analytes in the spot or band. Physical methods such as fluorescence under ultraviolet light are also often applied. The possibility of confirmation of identity based on at least two criteria is the essential advantage of TLC. The colorimetric reactions of drugs, narcotics, and other substances of clinical interest with different visualiza-

tion reagents are listed in Table 2. Identification can also be made using spectroscopic techniques such as TLC/FABMS or FABMS-MS (fast atom bombardment mass spectrometry or tandem mass spectrometry).

Densitometric measurement of the *in situ* fluorescence or absorbance provides information about the quantity of an analyte in a chromatographic band. Such measurements are suitable for the quantification of drugs such as chlorpromazine, tricyclic antidepressant and anticonvulsant in blood serum and plasma. Quantitative analyses are also performed by combination of TLC with other analytical techniques, e.g. UV-densitometry.

Applications

In a view of the complexity of clinical analysis, it is not possible to cover all applications extensively. Therefore, only the most important applications of TLC in clinical medicine analyses are presented. The criteria of aims of analysis are: (1) the diagnosis and treatment of hard intoxication, (2) screening research, (3) monitoring of therapeutic drugs concentration, and (4) evaluation of the efficiency of new methods of therapy. In such applications, the drugs and their metabolites, carbohydrates, amino acids, bile acids, lipids, porphyrins and other compounds of clinical interest are analysed. The results of such work are collected in libraries (databases) that significantly facilitate diagnosis and therapy.

The Diagnosis and Hard Intoxication Treatment

The term hard intoxication is applied to the determination of harmful effects, arising in a short time after introducing a large dose of poison to the body. These effects are mainly observed after drugs or alcohol overdose or the introduction of organic solvents, pesticides, etc., into body. The symptoms of intoxication can be similar to those caused by disease so that diagnosis based only on clinic symptoms is insufficient; in such situations analytical data are very important. Only laboratory results, can determine the type and concentration of poison in a biological material or a functional disorder caused by overdose intoxication or poisoning. The biological samples, where poisons and/or their metabolites are found are mainly blood or urine. The most important features of such analyses are the necessity to determine the type of poison as quickly as possible. The basic requirement (especially in analysis followed by diagnosis) is for information about the poison, from simple, rapid and reliable qualitative or semiquantitative methods. The common use of TLC in clinical medicine analyses of hard intoxication is due to its ability to provide such data.

Table 1 The applications of thin-layer chromatography (TLC) in clinical medicine research. The representative examples of separations

No.	Matrix and analyte		Chromatographic system		Type of development
	Analyte	Body fluid	Stationary phase	Mobile phase	
1	Theophylline	Serum	Aminopropylsiloxane modified silica	Ethanol–5% aqueous diethylamine solution (95 : 5)	One-dimensional, isocratic
2	Tetrahydrocannabinol (THC) metabolites	Urine	HPTLC silica gel	SPE elution solution: ethyl acetate–concentrated ammonium hydroxide (98 : 2) Developing solution: heptane–ethyl acetate–glacial acetic acid (7 : 3 : 10)	Toxi-Prep system: incorporate SPE with direct spotting onto TLC plate, one-dimensional, isocratic elution
3	Bile acid	Bile	Silica gel	Chloroform–methanol–acetic acid (85 : 20 : 9)	One-dimensional, isocratic
4	Porphyrins	Urine, faeces	RP-HPTLC (C-18 bonded wettable phase)	Acetonitrile–ion-pair reagent (IPR)–acetate buffer pH4.1 (9 : 5 : 5) IPR = <i>N</i> -cetyl- <i>N,N,N</i> -trimethylammonium bromide	One-dimensional, isocratic
5	Amino acids	Urine	Cellulose	(I) Pyridine–acetone–aqueous ammonium hydroxide–water (13 : 8.5 : 2.5 : 6) (II) Isopropanol–formic acid–water (25 : 3 : 2)	Two-dimensional, isocratic
6	Amphetamine derivatives	Urine	Aminopropylsiloxane modified silica	(I) Ethanol–triethylamine–hexane (15 : 9 : 76) (II) Acetone–triethylamine–hexane (23 : 9 : 68)	Two-dimensional, isocratic
7	Lipids	Sebaceous gland	Silica gel with concentrating zone	Hexane–diethyl ether–acetic acid (80 : 20 : 1)	One-dimensional, isocratic
8	Prostaglandins	Serum	HPTLC silica gel	Ethyl acetate–diethyl ether–benzene–dioxane–hexane (45 : 12 : 5 : 8 : 30)	OPLC one-dimensional
9	Amino acid derivatives	Urine	Silica gel	Chloroform–methanol–ethyl acetate–acetic acid	AMD gradient elution
10	Barbiturate derivatives	Serum, urine	HPTLC silica gel	(I) Ethyl acetate–ethanol–hexane (2.5 : 2.5 : 95) (II) Pyridine–hexane (2 : 8)	OPLC two-dimensional
11	Tetrahydrocannabinol (THC)	Urine	HPTLC I-silica gel WRFs II-silica gel F	(I) Dichloromethane–hexane–methanol (7 : 2 : 1) (II) Dichloromethane–hexane–methanol (7 : 1 : 2)	One-dimensional, isocratic
12	Ecdysteroids	Plasma	RP-TLC (C-2, C-8, C-12, C-18, aminopropyl, cyanopropyl bonded phases)	Methanol–water (9 : 1)	One-dimensional, isocratic

The majority of this work is aimed at the determination of analytical parameters of xenobiotics and/or their metabolites. In diagnostic tests using

TLC, identification is based mainly on comparison of R_F values and on visualization with specific colour reactions. Tests for the identification of alkaloids,

Table 2 Examples of visualization and quantification

Analyte	Visualization method	Quantification	
		Yes	No
Amino acids			
Common protein amino acids	3-Phenyl-2-thiohydantoin (PTH) derivative, 270 nm absorption		X

barbituric acid derivatives, benzodiazepine derivatives and other drugs from other pharmacological groups have been known for many years.

Mathematical methods have recently been applied in the diagnosis of hard intoxication. The first step of these methods is to evaluate the R_F values in two, three and sometimes four chromatographic systems. These systems must be carefully selected to ensure an appropriate distribution of R_F values across the plates, the reproducibility of the measurement of these parameters and the correlation of chromatographic properties between systems. Next, the sets of correlated R_F values are determined (experimentally determined R_F values are converted into correlated

R_F values by a graphical standardization procedure) in a possibly large group of substances. In case of clinical analyses there are usually hundreds of drugs and their metabolites. A mathematical function (e.g. 'discriminating power' or 'principal component analysis') for calculation of analytical data is then chosen. The data set obtained allows for relatively rapid identification of investigated (unknown) xenobiotics. A full description of the application of such methods can be found in the work by de Zeeuw *et al.*

TLC as a Screening Method

Screening methods reduce the cost and time of analysis of numerous groups of samples. In clinical

medicine analysis, this term is referred to a set of biological samples (laboratory screening methods) or to a set of individuals endangered by contact with harmful substances (metabolic screening). In both cases, the aim of analysis is the exclusion of a particular sample (for an individual) from the set of samples (individuals), which should be examined with great care. Application of TLC to such aims is attractive as this technique enables simultaneous analysis of several samples.

Laboratory screening methods are similar to diagnostic analyses, but the object of investigation is usually known. During the screening other properties such as changes in the body under xenobiotics influence, e.g. changes in enzyme activity, creation of methemoglobine, increased porphyrin expulsion, etc. are measured. Because drugs or their metabolites are excreted and concentrated in urine, this is the matrix most commonly used for such examination. Especially useful for screening investigations are kits such as the Toxi-Prep (TP) kit, proposed by Steinberg and coworkers which can simultaneously extract up to

seven specimens. The method is based on TLC and involves five major steps: solid phase extraction, concentration, spotting, development of chromatograms and detection.

The kits have been found to be particularly useful for analysis of basic and neutral drugs. The comparison of the usability of three kits (TL-A, TL and TP) in the monitoring of basic drugs is presented in Table 3.

Another example of screening methods is the detection of an unknown, potentially toxic xenobiotic in the presence of a number of endogenous substances. Such defined screening methods are focused on limiting the number of expensive methods of analyses.

Metabolic screening is based on observation of changes in biochemical profile of patients within a relatively short time. The commonest analyses are for cholesterol and lipids or amino acids and porphyrins. An example of such an application of TLC is the work of Lai *et al.* They proposed a simple test for the determination of porphyrins (porphyrins play a crucial role in the biological processes of haem synthesis; in the case of defects in the biosynthetic

^bNumber of times definitively identified (questionable identifications).

pathway of haem an increase of porphyrin excreted is observed). Numerous groups of people are occupationally exposed to the substances causing porphyrias, and these have to be periodically screened. The urinary porphyrin-free acids are separated on a RP-HPTLC plate coated with C_{18} bonded silica gel. The mobile phase is buffered (pH 4.1) with a ternary mixture (acetonitrile, ammonium acetate buffer, ion-pairing reagent). Porphyrins, separated by TLC, create spots with a characteristic profile (fingerprints), and these profiles (differing in the quantity of excreted porphyrins) are observed in porphyria (Figure 1). By observing chromatograms in UV light, the basic criteria of metabolic screening can be fulfilled.

TLC has the advantage over other methods in that it can screen for many drugs simultaneously, with a relatively high sensitivity, and can handle several samples per plate.

Drug Concentration Monitoring

The pharmacological action of many drugs depends not on the amount taken but on the concentration in the blood. Relations between these two values (dose and therapeutic concentration) depend on the drug and often have individual characteristics. It was found that after taking the same dose of phenytoin (drug in anticonvulsants) its concentration in patients blood differed more than twentyfold. Therefore, one of the tasks of clinical medicine analyses is to establish relationships between the concentration of the drug in blood and its dosage. Such analyses are called drug concentration monitoring. They are performed mainly on the dosage of drugs of little therapeutic value, combined therapy, etc. Drug concentration monitoring requires use of relatively simple, cheap

and rapid methods, which indicates the special suitability of TLC for such analysis. Drug concentration monitoring requires (in contrast to diagnostic and screening methods) quantitative analysis.

A good example of the application of TLC for drug concentration monitoring is the work by Krauss *et al.* on baclofen and its fluoro analogue (these are centrally acting muscle relaxants, which are used for the treatment of spastic disorders). Gas chromatography with electron-capture detection requires a time-

consuming separation and derivatization step; HPLC does not require derivatization but the detection limit is insufficient for such studies. Several enantiospecific methods have also been developed but their applicability to biological material has not been shown. The method proposed by Krauss is based on fluorescent derivatization of the drug with benoxapropen chloride, TLC separation of the resulting amides and their quantification by direct measurement of the fluorescence. This method requires extensive purification of the samples (e.g. solid-phase extraction) in order to remove interfering endogenous amino acids. Chromatograms are obtained with a stationary phase of silica gel 60 without a fluorescence indicator (plates with concentrating zones) and a mobile phase of diisopropyl ether–2-propanol–tetrahydrofuran, 90 : 6 : 5, v/v. After development, both compounds

were separated from constituents of the biological material (Figure 2). The fluorescence intensity of the derivatization products is sufficient to determine plasma concentrations over a suitable period of time after single dose administration of both drugs. The detection limit (10 ng mL^{-1}), linearity (60 ng spot^{-1}) and method deviation have been estimated. The applicability of the method has been proved by investigating plasma (and urine) samples of two volunteers after oral administration of 20 mg baclofen as a single dose. Full suitability of the method for pharmacokinetic routine analyses was demonstrated.

Evaluation of the Efficiency of New Methods of Therapy

Evaluation of the efficiency of new methods of therapy mainly concerns drugs newly introduced into

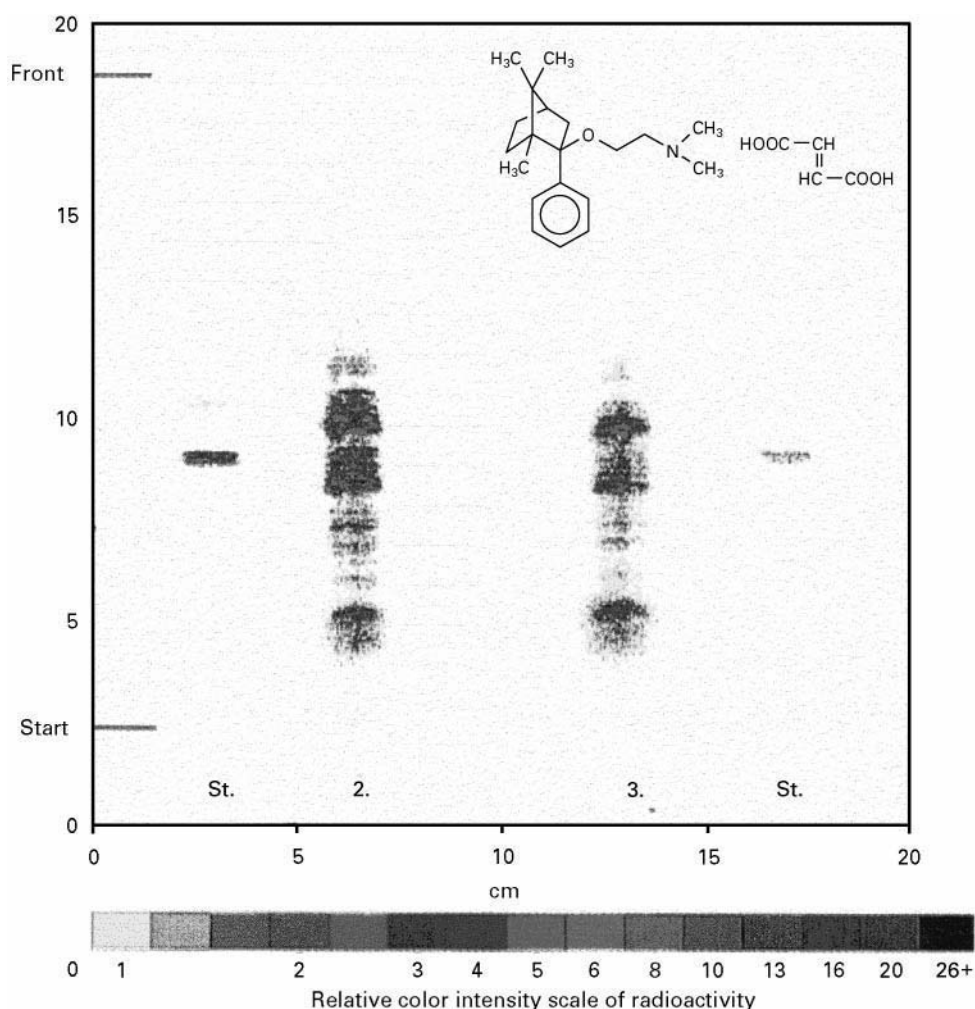

Figure 3 (See Colour Plate 70). OPLC–DAR profile of dog urine extracts. Sample, dog urine samples after 10 mg kg^{-1} oral dosing of ^{14}C -daramciclane. clinical medicine. From an analytical point of view it is a more complicated process than drug concentration monitoring since the object of investigation is not only concentration of the drug in blood but also its assimilation and excretion, harmfulness, metabolism, etc. Such investigations are performed mainly on blood and urine samples.

An interesting example of abilities of TLC in the above applications is the work of Szűnyog *et al.* They applied a combination of overpressure-layer chromatography (OPLC) with the relatively high sensitive and rapidity of digital autoradiography (DAR). Biological samples were analysed after one- or two-dimensional separation. Using the example of deramciclane (a new anxiolytic compound) they demonstrated, that the proposed method could be successfully used for study of *in vivo* metabolism in different phases of studies. The main advantages of the method were the extremely rapid separation and purification by OPLC, the possibility of the quantitative evaluation of metabolites over a wide linear range, visual and numeric comparison of metabolite profiles in various biological matrices and cost-effective metabolism studies (Figure 3).

TLC as a Clean-up Technique

The basic method of applications of TLC as a clean-up technique consists of the preparative separation of analytes and removal from the TLC plate together with adsorbent and elution with an appropriate solvent. This technique is used mainly in pharmacological work. In clinical medical analyses the method is used to separate mixtures and then

introduce the fractions obtained to other analytical instruments. From the analytical point of view, in these methods TLC has the role of a clean-up technique.

In analytical practice two basic methods of TLC combined with other analytical methods are applied. The older method of off-line coupling is similar to preparative cleaning of the sample. Eluate obtained after chromatographic separation and sorbent separation is introduced into the analytical instrument. The technique should be used when the recovery of an analyte is of secondary importance. An advantage of off-line methods is the possibility of performing analysis with optional detectors. In on-line methods the TLC plate is introduced to the detector step-by-step. Analytes are removed from the adsorbent by cathode sputtering or laser desorption. An important advantage of such methods is the full quantitative analysis of practically all substances of clinical interest. Unfortunately, these techniques are expensive and require very specific injectors that are not usually commercially available.

Martin *et al.* applied TLC coupled with MS-MS to the analysis of antipyrine and its metabolites in extracts of human urine. The urine samples were obtained from a volunteer who had received a single oral dose of antipyrine. After 12 h, an aliquot was enzymatic hydrolysed to liberate the analytes from glucuronide conjugates. Next, analytes were extracted (LLE), concentrated and separated by TLC. A good separation (Figure 4) was obtained on silica gel HPTLC plates with a mobile phase of chloroform-methanol-trifluoro-acetic acid, 95 : 5 : 1, v/v.

Figure 4 Chromatograms obtained from (A) a urine sample following enzymic hydrolysis and solvent extraction and (B) a standard mixture of the analytes and the internal standard: o, origin; sf, solvent front; 3OHA, 3-hydroxyantipyrine; DMAA, dimethylaminoantipyrine; A, antipyrine; 4OHA, 4-hydroxyantipyrine; NORA, norantipyrine. Reprinted from Martin P, Morden W, Wall P and Wilson I (1992) *Journal of Planar Chromatography-Modern TLC* 5(4): 255-258, with permission.

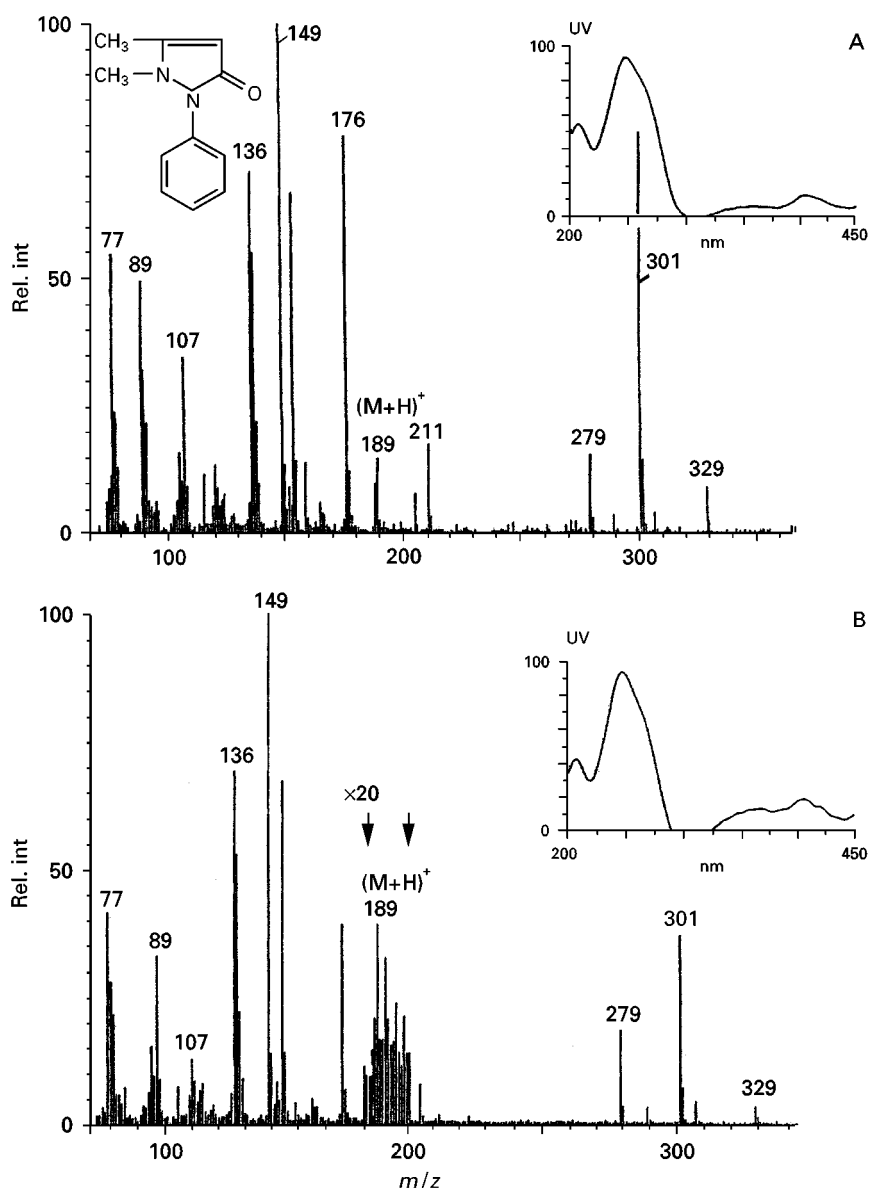

Figure 5 TLC-FABMS spectra obtained directly from the silica gel for (A) antipyrine and (B) material co-chromatographing with antipyrine from the urine extract (insets: structure and UV spectra). Reprinted from Martin P, Morden W, Wall P and Wilson I (1992) *Journal of Planar Chromatography-Modern TLC* 5(4): 255-258, with permission.

The appropriate areas of the plate were then removed for further analysis by FAB MS and FAB MS-MS. The authors demonstrated (Figure 5) that this relatively simple technique would appear to make TLC-FAB MS-MS eminently suitable for confirming the identity of drug metabolites in body fluids for the study of drug metabolism or the detection of drugs abuse, etc.

Conclusions

The analytical tasks connected with clinical needs are very large. It is estimated that the annual increase

in the number of such analyses is about 15-20% with systematic increases in the number of different clinical chemical parameters. However, not all clinical analyses can be performed using TLC. TLC is relatively simple, comes with low equipment cost, and has both a high efficiency and sensitivity. Some disadvantages of TLC include only fair specificity and the requirement of skill in accurately recognizing drug patterns by interpreting the coloured spots visualized with selective reagents, etc. It should also be emphasized that TLC is a comparative method; more complicated tasks in clinical medicine (investigation of metabolism and metabolite

structure) can be performed by this method but only in combination with other, mainly spectroscopic, analytical techniques.

CLINICAL DIAGNOSIS: CHROMATOGRAPHY

I. D. Watson, University Hospital, Liverpool, UK

Copyright © 2000 Academic Press

Clinical laboratories within the UK are responsible for providing services for the diagnosis and monitoring of disease. There are several specialities within clinical laboratories or pathology: haematology – examining blood cells and factors relating to blood cell production; biochemistry – measurement of metabolites, hormones, drugs, proteins; histopathology – examination of tissues and cells, usually microscop-

ically; immunology – assessment of antibody status in disease; molecular biology and cytogenetics – specialist services looking at genetic disease. Of these departments, the clinical biochemistry repertoire is the most amenable to chromatography.

Clinical biochemistry laboratories in an average district general hospital perform over a million analyses per annum. The large volume of samples (average request/analysis ratio ~1:4) received each day, the clinical demand for rapid turnaround plus the need for analytical imprecision of less than 5% with acceptable relative accuracy means that high levels

Table 1 Analytes, methodology, volume and cost: Illustration of a 'typical' clinical biochemistry laboratory workload, ranked in order of cost

Analyte	Tests per day (approx)	Method	Cost/test ^a (approx)
Urea and electrolytes (Na ⁺ , K ⁺)	4000	Automated wet chemistries and ion-selective electrodes	£1.00 each, i.e. £4.00 profile
C-reactive protein	50	Automated nephelometry	£4.00
Thyroid function (thyroid stimulating hormone, thyroxine)	200	Automated non-isotopic immunoassay	£5.00
Bedside device for a single drug of abuse	1	Immunochromatography	£5.00
Serum proteins	30	Electrophoresis	£15.00
Drugs of abuse	30	Automated immunoassay and chromatography	£15.00
Haemoglobin A _{1c}	50	Automated chromatography	£10.00

^aCost includes consumables, reagents, labour overheads and equipment depreciation.

of automation are not only desirable but essential. Most chemistries used are either wet chemistry or dry-film technology. The nature of certain analytes may make them less amenable to the high volume chemistries or the volumes of the rarer analytes make the development of automated chemistries more expensive or time consuming. Chromatography fits this last scenario in clinical laboratories. An illustrative workload pattern is presented in **Table 1**.

Clearly chromatography is utilized for those tests that are low volume and for which, generally, rapid turnaround is not required. **Table 2** illustrates the analytes, the mode of chromatography and reasons for use.

Thin Layer Chromatography (TLC)

Of all chromatographic techniques this is the best for parallel analyses enabling cost-effective high

throughput, yet surprisingly this potential has never been utilized apart from a few aficionados. Traditional TLC lacked chromatographic efficiency with consequent loss of resolution and lack of sensitivity. Widely used in many formative studies over 30 years ago, having replaced paper chromatography, it is still used for analytes such as testing drugs of abuse. To ensure reproducibility from plate to plate, commercial plates are used, often with a fluorescent indicator to aid detection although final detection relies on location reagents.

Nearly 20 years ago two developments still in current use greatly improved the utility of TLC: the advent and provision of HPLC column packing materials led to their introduction in TLC giving the anticipated high performance, i.e. high performance thin-layer chromatography (HPTLC). The improved resolution and sensitivity when coupled to significant improvements in densitometers and location re-

Table 2 Common current clinical chromatographic applications

Analyte class	Chromatographic mode ^a	Reason for use
Haemoglobin A _{1c}	LC	Most specific, rapid
Haemoglobin variants	LC	Specific for certain variants
Metabolites associated with inborn errors of metabolism	LC/GCMS	Specificity/flexibility
	LC-MS-MS	Introduced to selected centres as cost-effective and high specificity
Drugs		
Therapeutic drug monitoring	LC/GC	Cost/flexibility
Drugs of abuse		
Screening	TLC/HPTLC/GC	Specificity/flexibility/cost
Confirmation	GC/GCMS/LC-MS	Specificity
Toxicology	TLC/GC/LC	Flexibility
Markers of bone turnover	LC	Specificity, being superseded by immunoassay
Near patient testing devices, e.g. drugs of abuse	Immunochromatography 'stick' tests	Convenience

^aLC, liquid chromatography; GC, gas chromatography; MS, linked mass spectrometer; TLC, thin layer chromatography; HPTLC, high performance thin layer chromatography.

agents, meant that for the first time quantitative TLC with performance equivalent to GC or LC was possible. While some laboratories, particularly in Germany, enthusiastically adopted this technique it gained very few adherents elsewhere, particularly in clinical laboratories where the demand and skill base were inadequate.

Since the mid-1980s there has been an increasing problem of drug abuse. The initial assays developed for screening in the late 1970s used enzyme-multiplied immunoassay technique (EMIT), followed a little later by fluorescence polarization immunoassay (FPIA). These techniques were good for screening large numbers of individuals for a range of substances or classes of substances, e.g. cannabis, cocaine, opiates, benzodiazepines, barbiturates. The test for opiates was designed to detect heroin abuse but in fact it detects other opiates, i.e. codeine and dihydrocodeine, which are legitimately available. Clearly, therefore, any positive for this assay system, and also for others, requires confirmation. Immunoassay-based methods inherently depend on the specificity of their antibody and may not detect subtle structural differences between compounds leading to false positives. This clearly has implications for the subject tested, whether for clinical, forensic or employment purposes. It is now a firmly established principle, regrettably not always adhered to, that before taking action confirmation with a non-correlated technique should be performed. Chromatography is the technique of choice.

In clinical testing, HPTLC with appropriate location reagents and visual inspection is adequate as a confirmation technique, although this would usually be supported by other chromatographic modes. HPTLC also enables screening for many of these compounds not detected by the immunoassay screens; consequently HPTLC is a dynamically utilized

method in clinical laboratories performing substance abuse testing (Figure 1).

However, the other development in TLC was the development of a cellulose-based commercial system with a stylized Marquis reaction with reference to R_F and sequential colour changes collected in a compendium. This system was developed for clinical toxicology work allowing it to be performed by the non-specialist. In overdoses it works well despite its lack of chromatographic efficiency. Unfortunately the system was inappropriately applied to drugs of abuse testing which has greater sensitivity and specificity requirements and external quality assurance data consistently demonstrate poor performance.

In clinical practice, knowledge of which drug has been taken as determined by laboratory studies is useful for only a very few drugs and the concept of screening, usually using chromatography, is no longer commonly performed in the UK; in difficult cases, however, this is the preferred method of investigation.

TLC has a further unique property in clinical investigation. The plate complete with separation can be sent from the original investigating laboratory to a reference centre which will be able to investigate directly (perhaps using TLC-MS-MS) (Figure 2) any difficulty to identify/confirm spots. Currently this type of approach is a neglected area.

Gas Chromatography (GC)

The heyday of GC in clinical laboratories was in the 1970s. Biological fluids contain proteins in high concentration ($\sim 75 \text{ g L}^{-1}$) in a complex mixture of endogenous and exogenous metabolites and the compound of interest may be nonvolatile and present in low concentrations. The trick therefore was to extract the compound of interest quantitatively, make it vol-

Figure 1 HPTLC of extracted urine from drug abusers. Morphine, the principal metabolite of heroin, is indicated with an arrow.

atile and chromatograph it. Method development could take many man-hours and while some automation pre- and post-chromatography could be performed, these were labour-intensive methods best suited to low molecular weight metabolites. In the 1980s with increasingly better LC systems, GC usage in clinical laboratories went into decline.

Continued use of GC is necessary for a few analytes, however. Methanol, ethylene glycol, propanol and ethanol poisoning present overlapping clinical pictures; knowledge of which alcohol has been taken and how much is vital. GC with flame ionization detection is the ideal method giving rapid, reliable results and can be utilized in an emergency situation (**Figure 3**). Some laboratories still use GC for drug analysis.

Capillary GC with flame ionization and/or nitrogen-phosphorus detectors offers high sensitivity and in the latter case good specificity for determining biological analytes. Applications cover substance abuse, therapeutic drug monitoring and intermediate endogenous metabolites. However, GC-MS as bench-top analysers, either ion-trap or quadrupole, are becoming more common, though they are still rare, in clinical laboratories. The main reasons for the poor uptake of this combination are cost, demand and staff skills required.

As noted in Table 2 intermediate metabolites found in inborn errors of metabolism which can lead to significant morbidity and mortality, are currently detected by capillary GC. Early detection is vital, and although family screening can now be performed by

molecular biology, many cases are sporadic mutations requiring resolution for the optimal care of that individual. Failure to achieve this results not only in incapacity for the individuals and their family, but also in significant costs to the health service.

Capillary GC is satisfactory for a clinical service for drugs of abuse although GC-MS is essential in any forensic or employment issues, in which some clinical laboratories are involved.

Figure 3 Gas chromatography of alcohols in blood. (Reproduced with permission from Tames F.)

Liquid Chromatography (LC)

Liquid chromatography, with its wide range of modes and better biocompatibility than other chromatographic methods, has been utilized in clinical laboratories. Classical column chromatography was used in sample preparation of many of the standard wet chemistry methods in the past. Protein isolation using affinity chromatography enabled isolation of antibodies and subsequent labelled antibodies to provide the first radioimmunoassays in the 1950s and 1960s. Moore and Stein in 1954 developed an amino acid analyser which was refined over the years. Although primitive by today's standards, it enabled the first reliable measurement of the common amino acids allowing investigation into their metabolism, role in nutrition and relevance in inborn errors of metabolism. Amino acid analysers were automated with post-column reaction for detection and to a limited extent specificity. Much of the basic knowledge learnt through this pioneering work formed the basis for subsequent biological applications of LC.

Ten to fifteen years ago LC was making a significant impact in research-orientated clinical laboratories. Initially work focused on reversed-phase materials with many publications on the separation of a wide variety of drugs, endogenous metabolites and steroid hormones. A major difficulty was sensitivity and there was no true universal detector, nonetheless therapeutic drug monitoring already expanding due to the availability of EMIT technology consolidated using LC procedures for previously difficult analytes. A classic example was the common anticonvulsant carbamazepine which suffered thermal degradation on GC leading to significant imprecision. This was resolved by using LC. Additionally, it became readily possible to measure several drugs simultaneously. While this had been done using temperature-programmed GC it was frequently necessary to derivatize compounds to obtain satisfactory volatility and polarity and this could affect the selectivity. LC enabled the same approach, initially using solvent gradient programming on underivatized samples, often with minimal sample preparation. This approach enabled separation of a full range of anticonvulsants: ethosuximide, primidone, phenytoin, phenobarbitone and carbamazepine and their metabolites (Figure 4).

This meant that efficient processing, all samples followed the same analytical track, reduced costs per analyte and the occasional detection of inappropriate medication. In this particular area the wide and increasing range of nonisotopic immunoassays compatible with automation has meant many clinical laboratories find it more organizationally efficient to perform these assays by automated immunoassay; a hard

Figure 4 Isocratic liquid chromatography of anticonvulsants in serum. Analysed on Gilson ASTED system with sample pre-dialysis and trace enrichment prior to chromatography. (Reproduced with permission from O'Connell, D.)

core still use LC, though whenever possible using an automated system. Surveys through the UK National External Quality Assurance Programme have consistently shown LC methods to have the best accuracy with acceptable imprecision. The introduction of new anticonvulsants, e.g. lamotrigine, has led to a demand for analysis. This has meant development of LC assays demonstrating the role of chromatography in development of clinical investigations.

This is a common scenario in method development in that research or reference centres develop an LC assay for a new analyte to detect or monitor disease. As the utility of this determinand is demonstrated, demand rises, causing processing difficulties for the reference centre, parallel to an increasing demand from less specialist centres. Some will invest in an LC solution but the reagent manufacturers are alerted to the developing interest in the analyte. Knowing that clinical laboratories have a predilection for rapid, automated large single or multiple similar medium analysers, they develop wet chemistry or immunoassay methods. This approach will be reagent expensive but require minimal labour utilizing pre-existing equipment. Once this is marketed and adopted the LC procedure, albeit more accurate, declines and may be dropped altogether.

A further illustration of this is the measurement of bone turnover; the original analyte hydroxyproline was determined by a cumbersome, manual, wet chemistry assay. As interest grew in hormone replacement therapy effects in osteoporosis much effort was expended in developing a gold standard LC assay for pyridinoline and deoxypyridinoline. There were

particular problems, eventually resolved, with obtaining a satisfactory internal standard. This has become established as the reference method, but is now being supplanted by immunoassay measurement of deoxyproline.

Screening methods using LC have suffered from the lack of reproducibility between reversed phases. The REMEDI system for drug abuse screening is however an established screening technique linked to a linear diode array with spectral library and has been shown to provide satisfactory identifications on screening for drugs.

The detection of inborn errors of metabolism by reference paediatric biochemistry laboratories has hitherto relied heavily on GC-MS with all the inherent problems plus the need for separate assay condition for different compound classes, e.g. organic acids and amino acids. Recently the NHS Research and Development Programme – Health Technology Assessment – after an evidence-based medicine research exercise, has indicated that LC-MS-MS would deliver appreciably greater benefits than current systems for the detection of a variety of different forms of inborn error of metabolism. Hitherto, funding for such equipment had been stalled on the capital cost, but demonstration of the economies delivered by LC tandem MS argued in favour of the system which is now being introduced in selected centres. It is such economic analyses that may progress and sustain chromatographic methods in the face of a decreasing skill base and drive for consolidation in clinical laboratories.

An example of where the specificity of LC is valued and is allied to an improvement in efficiency is the analysis of haemoglobin A_{1c} (Hb A_{1c}). Hb A_{1c} is glycated haemoglobin A, and is a long-term measure of control in diabetes mellitus. Recent international advice has called for close control of Hb A_{1c} in diabetics and requires an accurate and precise method. Early studies on Hb A_{1c} used classical column chromatography on mini-columns, this was labour intensive and commercial 'kit' LC solutions began to be offered. Soon an automated wet chemistry analyser compatible methods were developed and embraced.

However, significant proportions of the population, depending on ethnic mix, do not have haemoglobin A as their sole haemoglobin and to assess glycaemic control one must look at the glycation of the variant haemoglobin; the wet chemistry method cannot do this. There has therefore been a resurgence of interest in the 'kit' LC solutions; popular ones use anion exchange chromatography which have run times of 4 min providing full sample automation for over 250 samples per day (Figure 5).

Figure 5 Ion exchange chromatography of haemoglobin A_{1c}, an indicator of glucose control in diabetics. Hb A_{1c} retention 1.75 min.

As diabetic assessment is performed regularly and many organ systems are examined, it is not uncommon for blood to be drawn from a patient and the Hb A_{1c} to be measured in the clinic using LC while they wait. This provides the clinician with the result when seeing the patient and improves the patient throughput.

Immunochromatography

Immunochromatography is the preserve of research laboratories as a laboratory technique. Near-patient testing, however, utilizes commercially produced

Figure 6 Immunochromatography slide for once-only use near the subject testing to detect abused drugs. C = control, THC = tetrahydrocannabinol, a metabolite of cannabis.

'sticks' which use immunochromatography. The principle is that the sample, e.g. urine, is applied to the stick which is then developed, e.g. by capillary attraction, the analyte of interest binding at a zone where there are antibodies. There are sometimes built-in

positive and negative controls. When the antigen and antibody combine they develop a visible colour spot or band which confirms the presence of the compound of interest (**Figure 6**). While these devices are expensive and inaccurate they have the benefit of immediacy which may be clinically acceptable provided they are used appropriately.

The Future

Chromatography has maintained its role in certain niches in clinical laboratories. Interest in manufacturer-supplied solutions for chromatography, particularly LC, exists and compensates for the lack of skill base. For difficult low throughput analyses this may be how developments will be consolidated. Capillary zone electrophoresis could impact on much current LC work but again skill and capital costs militate against this. If accuracy rather than imprecision becomes a major clinical laboratory issue, as it may, then the inherent accuracy of chromatography probably linked to mass spectrometry will provide a role for definitive methods and may provide a role for methods used in routine laboratories.

COAL: FLOTATION

B.K. Parekh, University of Kentucky, Lexington, KY, USA

Copyright © 2000 Academic Press

Introduction

The process of froth flotation for upgrading the quality of coal by removing mineral matter (ash and

pyrite) has received increased attention since the 1960s. The froth flotation process is typically used for treating <0.5-mm size coal and is currently the only technique both effective and economical to clean coal on a commercial scale. In the USA, the majority of coal preparation plants discard the <0.5-mm coal owing to the high cost of processing of the fine coal.

Recovering fine coal offers important economic and environmental functions. In economy terms, the plant recovers an extra amount of clean coal that would have otherwise been discarded to the impoundment. Recovering the clean coal reduces the amount of fines to the ponds, and improves the quality of recycled water.

The basic coal flotation technology has been derived from ore flotation, where the technology has been extensively used. The first froth flotation plant for coal was established in the United Kingdom in 1920 and the first US plant was established in 1930. Froth flotation technology has made substantial progress over the last fifty years.

Coal is a solid combustible material and exists in the ground along with impurities. Coal, being composed of carbon elements, is hydrophobic in nature and thus is a good candidate for the froth flotation technique. The impurities present in coal basically consist of clays, quartz, calcite, dolomite, pyrite, chlorite, etc. which are hydrophilic in nature and thus, can be easily removed in an aqueous medium. Pyrite minerals present in coal have an ambivalent character and are sometimes difficult to remove by the flotation technique.

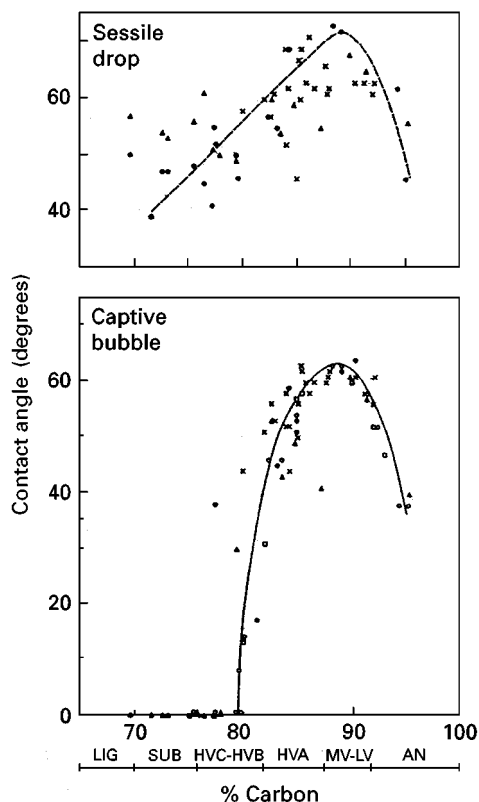

Figure 1 Hydrophobicity of various coals as a function of percentage carbon based on the contact angle technique. (Aplan (1989), courtesy of SME, Littleton, Colorado, USA.)

Hydrophobicity of Coal

The hydrophobicity of coal varies with the rank of the coal and oxygen functional group present in the coal. The high volatile bituminous coals are the most hydrophobic, whereas lignite is the least hydrophobic. One technique to quantify the hydrophobicity of coal is through measuring contact angles of water on coal surfaces. **Figure 1** shows the contact angle data of water on various coals. Note that the maximum contact angle or the hydrophobicity occurs at $\sim 88\%$ C, and the high-carbon content anthracite coals are less hydrophobic.

Zeta Potential of Coal

The zeta potential of various coals with respect to pH is shown in **Figure 2**. Note that the point of zero charge (PZC) is highly variable and depends on the source and type of coal. The sub-bituminous and lignite have a PZC of ~ 2 , whereas the high volatile (hva) bituminous and anthracite coals have a PZC of ~ 5 . In general, a reduction in the PZC value indicates a reduction in hydrophobicity.

Reagents

The purpose of flotation reagents is to provide a strong hydrophobic surface and to create small relatively stable bubbles. For coal flotation, in general, only the collector and frother reagents are used.

Collectors

Theoretically speaking, the highly hydrophobic coals (containing 85–90% C) should not require any collector. In practice, a small amount of either No. 2 fuel oil or kerosene is used as collector. The amount of a collector required varies from a low ($0.11\text{--}0.2\text{ kg t}^{-1}$) for a high rank coal to a high ($1.0\text{--}2.0\text{ kg t}^{-1}$) for a low rank coal.

Frothers

The primary function of the frother is to produce a large quantity of fine size bubbles. The bubbles should be able to carry the coal to the surface without breaking, and once out of the flotation machine, it should break down. The most commonly used frothers for coal flotation are either pure alcohol, e.g. MIBC (methyl isobutyl carbinol) or a mixture of various alcohols and the polypropylene glycol-based frothers. The amount of frother required varies from 0.2 to 0.5 kg t^{-1} .

Depressant

The function of depressant is to suppress the flotation of one component of the mixture of solids by adding a specific chemical. In coal flotation, pyrite usually floats along with the coal. Many papers have been published on the subject; however, Chaudhari and Aplan, and Xu and Aplan, have conducted a detailed investigation of various reagents for depressing flotation of pyrite. They concluded that there is no universal reagent for depressing pyrite. In the coal industry, pyrite depression is not practised; however, in the future this might become an important step for the coal industry to survive.

There are some other variables for flotation, such as pH, dispersing reagents, percentage solids, particle size, etc. However, in the coal industry, very little or no attention is given to these factors. Readers interested should refer to Aplan's work.

Flotation Machines

The coal industry uses either mechanical or column cells.

Figure 3 A line diagram of a column flotation cell.

Mechanical

The most commonly used flotation machine is one in which a mechanically driven impeller agitates in the pulp and disperses air into it. The major development in mechanical flotation cells has been in the design of

Figure 4 Schematic diagram of the Microcell™. (Yoon *et al.* (1992), courtesy of Gordon and Breach Science Publishers.)

Figure 5 Schematic of Jameson cell. (Courtesy of Richwood Industry, Huntington, West Virginia, USA.)

larger volume machines (3000 ft³ or 84 m³). For coal flotation, mechanical cells are usually arranged in banks of four to six cells in an 'open-flow' arrangement.

Column

The column flotation cell which has achieved success in the mineral industry was introduced to the coal industry in the 1990s. The machine consists of a long (~6 m) vertical tube ranging from 2.4 to 3.0 m in

Figure 6 Performance data of the Jameson cell at the laboratory, pilot, and full scale. (Honaker *et al.* (1999), courtesy of SME, Littleton, Colorado, USA.)

diameter. Figure 3 shows a sketch of the column flotation machine. The feed (coal slurry containing flotation reagents) to the column is introduced at about the 5-m level. The froth height is maintained close to 1 m and wash water introduced into the froth layer to remove any entrapped and entrained impurities. The tailings containing the impurities (ash) are discharged at the bottom of the column. A variety of column flotation machines have been developed over the last few decades. The Ken-Flote column developed at the University of Kentucky Center for Applied Energy uses either a porous cylinder or a 'foam-jet' system to generate bubbles and provides a quiescent zone for attachment of coal particles to the air bubbles, which keeps ash entrainment to a minimum. In 1989, the first commercial Ken-Flote

(Mohanty and Honaker (1999), courtesy of Elsevier Science.)

columns were installed in the USA at the Powell Mountain Coal Company, Virginia.

The 'Microcel' column flotation developed at the Virginia Polytechnique and State University uses an inline mixture to generate fine bubbles in the column. In this column, a part of the reject stream is passed through the inline mixture along with the frother and air to generate fine bubbles. **Figure 4** shows a diagram of the MicrocellTM column.

The Static Tube flotation system developed at the Michigan Technology University uses corrugated plates packed inside the column to break up large bubbles into a smaller size bubble. The machine does not utilize any special bubble-generating device.

The Jamison cell is a column cell that is much shorter than any of the columns described earlier. As shown in **Figure 5**, the Jamison cell utilizes a pressurized feed stream injected through a long tube called the downcomer to draw atmospheric air into the device. The resulting jet formed is discharged into a short column where coal floats to the surface and tailings are discharged at the bottom. Wash water is generally added through a tray located above the froth phase. Currently, quite a few Jamison cells are being used in Australia and a few coal preparation plants in the USA. **Figure 6** compares the separation performance as a function of ash content for a coal using the laboratory-, pilot- and full-scale Jamison cell units. The L-shape of the release curve indicates that the impurities in the coal are well liberated. The laboratory- and pilot-scale units were nearly able to produce the performance of the release

analysis. An ash content reduction of about 40–45% was achieved while recovering 77% of the combustible material, which equates to an ash rejection of about 95%.

Mohanty and Honaker published a comparative evaluation of the three leading column flotation technologies. According to them, the packed column produced the best separation performance owing to its ability to support a deep froth zone. However, because of the absence of an air-sparging system and consequently larger bubbles, the solids-carrying capacity of the froth was minimal. On the other hand, the solids-carrying capacity or solids throughput achieved with the Jameson cell, was found to be maximal. The MicrocellTM achieved maximum carrying capacity while providing a high energy recovery with a reasonably low amount of reagents. **Figure 7** shows the combustible recovery (amount of combustible material) as a function of product ash and total sulfur obtained for a coal using the three column technologies. The AFW (advanced flotation washability) is a limiting curve indicating the possible ash and sulfur that could be achieved using froth flotation technology. Note that the packed column provided both low ash and sulfur; however, the MicrocellTM and Jameson cell both provided high combustible recovery.

In all work on coal flotation, a high ash rejection has been reported using column flotation technology. However, removal of pyritic sulfur has been marginal. The main reason for this is attributed to the ambivalent nature of coal pyrite; some pyrites are

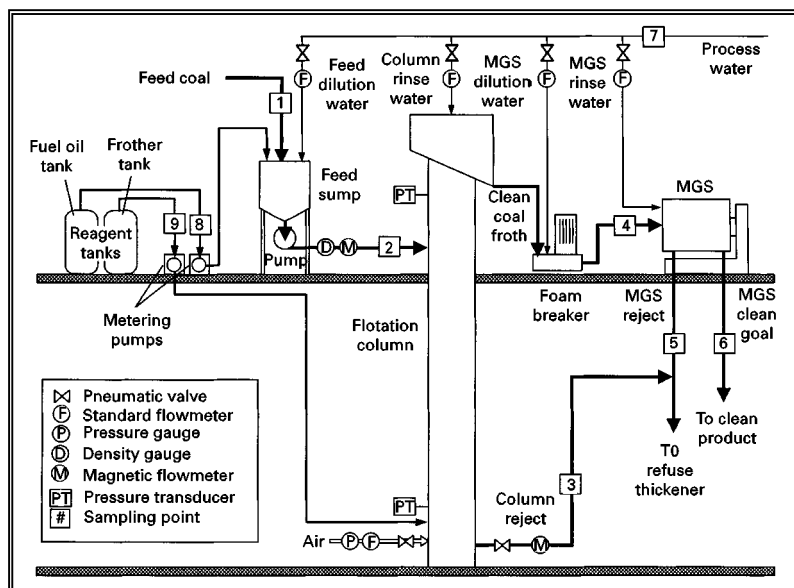

Figure 8 Schematic drawing of the combined advanced flotation/enhanced gravity separation circuit. (Luttrell *et al.* (1998), courtesy of Gordon and Breach Publishers.)

hydrophobic and some are hydrophilic in nature. In the case of coal, pyrite is always associated with some carbon which affords it hydrophobic and makes it float with coal. Luttrell *et al.* conducted studies on combining column flotation with an advanced gravity separation technology to remove pyrite from coal. The process flowsheet for the two-stage circuit is shown in Figure 8. A Microcell™ flotation column froth product after derating was sent to a multi-gravity separator (MGS) developed by the Mosley Ltd, UK. The MGS is similar to the shaking table, except that the particles in the flowing film are also subjected to centrifugal forces. Figure 9 compares the performance of the flotation column alone to that obtained using the combined flotation column/MGS circuit. The rejection of pyritic sulfur improved from 60.5% to 83.6% and ash rejection improved from 83.8% to 87.7% using the combined techniques. Using the MGS unit, the loss of coal (energy) was very low, in the order of 2–3% points.

Coal flotation is a manually operated process. Recently, process optimization has been achieved through more efficient circuit designs and innovative sensor development. Some new approaches have been developed in the sensor area, which help in designing a controlled reagent delivery system. The Consol Co. has developed an inexpensive optical-based system shown in Figure 10. The main components of the detector are a glass tube, a photoconductor, an opaque barrier, and a light-emitting diode (LED). The light from the LED is reflected from the slurry to the main photoconductor. The photoconductor changes resistance in proportion to the light reflected from the tailing stream. The higher the tailings slurry ash con-

Figure 10 Optoelectronic tailings detector. (Meenan (1999), courtesy of SME, Littleton, Colorado, USA.)

tent, the more light reflected back to the photoconductor and the lower the resistance.

A machine-vision or 'video-based' analyser system has also been successfully tested by Virginia Polytechnic Institute and State University. The video-based system could detect changes in slurries over an operating range of 60–90% ash.

Conclusion

In summary, coal flotation, column flotation has shown significant advantages from the technical and economic points of view. A combination of column with advanced gravity separators provides a much cleaner coal with low ash and pyritic sulfur contents. In the future, all new coal preparation plants will utilize column technology along with process optimization and sensors for the economic recovery of ultra-fine coal particles.

Introduction

When dealing with colloidal materials, the parameters of size and size distributions are needed, because many physicochemical processes, like aggregation and deposition on solid surfaces, are influenced by the size and size distributions of these materials.

For the analysis of submicron or supramicron colloidal particles, a sedimentation process, either under gravity or with centrifugal force, is necessary to sort different diameter particles into classes, and then to obtain an average size and a size distribution. Among the successful techniques used for this purpose, are electrophoretic mobility and the methods of size exclusion chromatography,

hydrodynamic chromatography and field-flow fractionation (FFF).

FFF is a family of separation methods introduced by Giddings in 1966, but several groups all around the world have contributed significantly to the development. The various subtechniques of FFF are best suited to the separation and characterization of colloidal materials and macromolecules, including biological components ranging in size from proteins to living cells, environmental colloidal particles, as well as industrial polymers and colloids, powders, latexes and emulsions.

Principles of FFF

FFF is a flow elution method with retention achieved by using applied fields to drive the solutes into quiet flow regions. The applied fields are able to achieve

the task of separation more gently and with more accurate control than the two-phase distribution forces used in chromatography.

Just as its name suggests, fractionation in FFF is the combined effect of an applied cross-field and the laminar parabolic flow profile of the carrier mobile phase. The separation process in FFF is carried out in a thin, unobstructed, ribbon-like channel with a rectangular cross-section and elongated extremities connected to capillary tubes allowing the continuous flow of the carrier liquid (Figure 1). Flow velocity is highest at the middle of the channel and lowest near the two channel walls. As the carrier stream moves through the channel, an external force field or gradient is applied perpendicularly to the flow, which pushes the components of the sample into the slower moving streams near the outer wall, so that they form a thin, steady-state layer against that wall.

The mean thickness of the layer is different for each distinct chemical or particulate species, and depends on the strength of the interaction between the field and the species and on the diffusion coefficient corresponding to that species. Larger colloidal species and macromolecules are usually forced more vigorously toward the wall than are smaller ones. This is the basis for selective retention in normal FFF, which produces in general an elution spectrum in which small particles are eluted first and large particles last, until steric effects dominate. At this transition point a foldback in elution order occurs, and the larger particles elute from the system before the smaller ones – a trend opposite to that observed in normal FFF. Steric FFF (StFFF) predominates when the particle radius exceeds the mean layer thickness of the solute,

such that the protrusion of the particle out of the flow system is determined by the particle's size rather than by its Brownian motion.

Sub-techniques of FFF

Among the various fields and gradients used to drive species to the channel wall, four specific kinds have been most developed, yielding a different subtechnique of FFF. Among those used are centrifugal or gravitational forces (sedimentation FFF = SdFFF), thermal gradients (thermal FFF = ThFFF), cross-flow (flow FFF = FIFFF) and electrical fields (electrical FFF = ElFFF). All these subtechniques can be worked under the normal mode of operation, in which the concentration distribution along the axis which is perpendicular to the carrier flow is exponential as a consequence of the balance between field-induced displacements and diffusion, or under the steric mode of operation in which the elution order is inverted relative to that observed for normal FFF. They can also be used in the hyperlayer and potential barrier modes of operation, which will be described in detail later.

Retention Theory

The peak retention in FFF can be expressed by the retention ratio, R , defined as the ratio of the void volume, V_o , to the component retention volume, V_R :

$$R = \frac{V_o}{V_R} \quad [1]$$

The retention ratio R in normal FFF is related to the dimensionless retention parameter λ ($\lambda = l/w$, where l is the mean layer thickness and w is the channel thickness) by the equation:

$$R = 6\lambda[\coth(1/2\lambda) - 2\lambda] \approx 6\lambda \quad [2]$$

The last approximation is valid for highly retained components. Eqn [2] is general for all FFF subtechniques, but as the parameter λ varies with the applied external field or gradient, the experimental parameter R is related to different physicochemical quantities of the sample under study, thus leading to the sample's separation depending on its interactions with the external field:

$$R = \frac{6kN_A T \rho_s}{MG\Delta\rho} = \frac{36kT}{d^3\pi w G \Delta\rho} \quad (\text{SdFFF}) \quad [3]$$

Figure 1 Schematic representation of the FFF channel with the parabolic flow profile in detail. Reproduced with permission from Giddings JC (1979) Field-flow fractionation of polymers: one-phase chromatography. *Pure and Applied Chemistry* 51: 1459.

$$R = \frac{6T}{aw(dT/dx)} = \frac{6D}{D_T w(dT/dx)} \quad (\text{ThFFF}) \quad [4]$$

$$R = \frac{6DV_o}{\dot{V}_c w^2} \quad (\text{FIFFF}) \quad [5]$$

$$R = \frac{6D}{\mu E w} \quad (\text{ElFFF}) \quad [6]$$

$$R = \frac{3\gamma d}{w} \quad (\text{StFFF}) \quad [7]$$

where M is the solute molecular weight, d is the Stokes diameter, $\Delta\rho = |\rho_s - \rho|$ is the density difference between the particle (ρ_s) and the carrier liquid (ρ), G is the field strength expressed in acceleration, T is the absolute temperature, k the Boltzmann's constant, N_A Avogadro's number, D is the solute-solvent diffusion coefficient, D_T the coefficient of thermal diffusion, a the dimensionless thermal diffusion factor, dT/dx is the temperature gradient applied at right angles to flow, \dot{V}_c is the volumetric cross-flow rate, μ is the particle's electrophoretic mobility, E is the electrical field strength, and γ is a dimensionless factor that accounts for the drag-induced reduction in velocity, and for the increase in velocity due to the activity of lift forces.

The above equations show that the solute parameters controlling retention, and thus characterized by retention, are M , d and ρ_s in SdFFF, D_T and a in ThFFF, D and d in FIFFF, μ and D in ElFFF, and d , γ in StFFF. As in all FFF techniques, the retention ratio is related to the particle size and the fractionation is based on particle size differences or on the D and D_T coefficients.

We note that all R values in the normal FFF mode are inversely proportional to the strength of the field or gradient employed: G , dT/dx , \dot{V}_c and E – therefore making possible the manipulation of the retention ratios by changes in field strength. This makes FFF applicable to many different sample types over a wide particle size distribution range. A wide variety of components can be handled within a run by applying field programming methodologies in which the field strength is gradually reduced during the separation.

In the present work, we focus on sedimentation FFF (centrifugal and gravitational) and flow FFF, which are the most usable and accurate for the separation and characterization of colloidal materials.

Instrumentation

Sedimentation FFF

The apparatus of SdFFF consists of a channel with highly polished walls and rectangular cross-section which is fitted to the inside of a centrifuge basket. Solvent is pumped into and out of the system with the aid of special low volume rotor seal and subsequently to a UV detector. The associated parts of the system (e.g. pumps, detectors, recorders, sample injectors) are readily available liquid chromatography components. At present, the SdFFF rotor can be operated at a maximum speed of 32 000 rpm, which corresponds to an applied field of approximately 85 000 g for the common rotors used. With such a rotor, colloidal particles as small as 0.005 μm can be retained and analysed, when their density is between 1.5 and 3.0 g cm⁻³. The upper limit of particle size is reached when the mean layer thickness becomes equal to or less than the particle radius, and steric factors determine the retention ratio.

In gravitational FFF (GrFFF) the earth's gravitational field is used and the apparatus consists of a channel formed between two glass plates separated by a Mylar spacer.

Flow FFF

In flow FFF the external field is simply the flow of a second solute stream perpendicular to the carrier stream. The walls of the FFF channel are constructed of semipermeable membranes, so as to accommodate the cross-flow and, at the same time, to retain solute particles in the channel. The semipermeable membrane material is the limiting factor in the performance of the flow FFF system.

Applications

SdFFF and FIFFF can be applied to the separation and characterization of spherical or irregular, monodisperse or polydisperse colloidal particles. The particle size analysis of colloids can be carried out successfully by working in the four modes of FFF.

Normal SdFFF

Normal SdFFF has been applied to many systems involving polymers, biological macromolecules (such as DNAs, virus particles and protein aggregates), subcellular particles, emulsions and a great variety of natural and industrial colloids. An example of SdFFF is shown in **Figure 2**, which illustrates the separation of colloidal polystyrene latex microspheres. No other method can yield comparable resolution for submic-

Figure 2 Separation by SdFFF of four polystyrene (PS) latex beads with the diameters indicated in the scheme. The experimental conditions were as follows: field strength 193.7 g; flow rate $12 \text{ cm}^3 \text{ h}^{-1}$; void volume of the channel 2.0 cm^3 . Reproduced from Giddings JC, Myers MN, Caldwell KD and Fisher SR (1980) Analysis of biological macromolecules and particles by field-flow fractionation. *Methods of Biochemical Analysis* 26: 79, with permission from Wiley and Sons, Inc.

ron particles. One of the advantages of SdFFF in characterizing colloids is the fact that they are separated into sharp fractions and that certain properties of each fraction can be deduced by the measurement of the fraction's retention time. Accurate characterization is possible without calibration because of the simplicity and theoretical tractability of the SdFFF system (cf. eqn [3]), when interactions between the particles and the channel wall are absent. Particle parameters subject to characterization include mass, density, polydispersity, diffusivity and various particle dimensions (number and weight average diameters, differential and cumulative size distributions).

A series of papers relating to colloid characterization by SdFFF has been published by Giddings. The first paper showed that relatively monodisperse colloidal populations can be characterized with respect to particle mass, diameter, density and polydispersity. Subsequent papers described methods for obtaining particle size distributions for polydis-

perse colloids and emulsions, and the separation and characterization of narrow populations or subsets within a polydisperse population of colloidal particles.

A wide variety of inorganic colloids of industrial importance, including ceramics, carbon black, quartz, clay silica, alumina, titania, haematite and hydroxyapatite, have been separated and characterized by SdFFF with high resolution in less than 15 min, under optimum conditions. SdFFF also permits analytical separations of submilligram quantities, and the separated components are easily collected for subsequent work. SdFFF can be used on a larger scale to separate quantities of the order of a gram of purified components. Fractionation and characterization by SdFFF of the submicron colloidal particles contained in natural waters have also been carried out. With the aid of an on-channel concentration procedure, SdFFF has been shown to be applicable to an area of analysis where the particle system in natural water is complex and the particles are present in much lower concentrations than in samples which can be analysed without the preconcentration procedure. Although particle diameter can be obtained by SdFFF only if the particle density is known, this apparent weakness can be converted into a major strength. By changing the density of the suspending medium, the difference between it and the density of the solute particles can be changed by known increments, and it becomes simple to split up the d parameter and $\Delta\rho$ terms of eqn [3]. Therefore, both particle size and density can be found by SdFFF.

Particle size distribution analyses have been carried out on a wide variety of suspended organic and inorganic particulates (such as polychloroprene and polymethyl methacrylate lattices, water-based titania and carbon black dispersions, phthalocyanine blue dyes) using the methodology of time-delayed exponential force-field sedimentation field-flow fractionation (TDE-SdFFF). Particle retention time in TDE-SdFFF correlates simply and accurately with the logarithm of particle size (diameter or mass). Relative to constant-field SdFFF, the TDE-SdFFF method provides the advantages of decreased analysis time and improved detection sensitivity, while maintaining adequate resolution for accurate differential and cumulative particle size distributions.

SdFFF has been also used for the kinetic study of aggregation of various inorganic colloids, including hydroxyapatite and sulfide samples. From the variation of the number average diameter obtained by SdFFF with time, rate constants for the bimolecular process of aggregation and stability factors of the colloids have been determined.

Normal FIFFF

FIFFF has been applied to a variety of species including silica gel, latex and virus particles, as well as proteins, protein clusters and water-soluble polymers. FIFFF has also been applied to humic materials, pushing the lower molecular weight limit to a few hundred. An asymmetric version of FIFFF has been introduced in which only one wall, the accumulation wall, is permeable to the liquid, whereas the other wall is solid. Thus, the cross-flow is generated by the fraction of the inlet flow that exists through the membrane. With this asymmetric system, various biological macromolecules and water-soluble polymers have been successfully analysed.

Steric FFF

StFFF represents the upper limit of the field strength applied. Although any effective field may be applied to the StFFF mode, the gravitational field represents the most practical means of utilizing the principle of StFFF to the analysis of particles in the diameter range 1–100 μm . The first experimental evidence for the applicability of StFFF was presented in 1978 by Giddings for the fractionation of glass beads having diameters 10–32 μm . Later the technique was applied to the separation of a mixture of spherical silica beads in the diameter range 5–14 μm , to the separation of a number of large particle samples, including chromatographic support materials and fine-ground coals, as well as to useful applications in biochemistry and biology (yeast cells, whole blood).

Recently, the StFFF technique has been applied to particle size analysis (number and weight average particle diameters, as well as differential and cumulative particle size distributions) of polydisperse supramicron particles of strengite ($\text{FePO}_4 \cdot 2\text{H}_2\text{O}$ with number average diameter of 3.5 μm), which is of great significance in natural waters, and mixed sulfides ($\text{Cu}_x\text{Zn}_{(1-x)}\text{S}$, $0 < x < 1$, with number average diameter in the range 5.7–7.6 μm), which are of paramount importance in industrial chemistry. The particle size distributions, which correspond to the longest axis of the needle-shaped $\text{FePO}_4 \cdot 2\text{H}_2\text{O}$ particles, found under various experimental conditions by StFFF, are in good agreement with those obtained by transmission electron microscopy (TEM). This confirms the feasibility of the StFFF technique for characterizing polydisperse, irregular, inorganic colloids, and verifies the general features of the theory.

From the variation of the number and weight average diameter of the $\text{Cu}_x\text{Zn}_{(1-x)}\text{S}$ particles deter-

mined by GrFFF with various parameters, such as solution pH and ionic strength, kind of detergent and time, in combination with microelectrophoresis measurements, useful conclusions about the stability and consequently the aggregation and deposition phenomena of these sulfides can be deduced.

In the normal mode of SdFFF operation the relationship between V_R and d can be established using eqn [3], without empirical calibration. In the steric mode of SdFFF (Sd/StFFF), calibration must be established empirically, as the steric correction factor in eqn [7] is unknown, increasing with the flow velocity and decreasing with the increase of field strength. As retention is based on particle density as well as size, a purely size-based calibration is not generally valid. By examining the balance between driving and lift forces, it is observed that an equal retention ratio is obtained for equal size particles subject to equal driving forces independently of the particle density. Thus, by adjusting the field strength G to compensate exactly for the density difference $\Delta\rho$, so that the product $G\Delta\rho$ in eqn [3] is the same for the sample and the standard polystyrene latexes, linear calibration plots of $\log(\text{retention time})$ versus $\log(\text{diameter})$ for the latexes can be used to characterize the sample under study. This calibration procedure for Sd/StFFF has been successfully applied to the rapid size separation and measurement of particle size distribution of various starch granules.

Hyperlayer FFF (HyFFF)

The sedimentation hyperlayer field-flow fractionation (SdHyFFF) technique differs from conventional FFF methods in that the solute zone is focused into a thin layer by the opposing forces of centrifugal acceleration and buoyancy in a density gradient, which is formed while the carrier is flowing through the channel. So an equilibrium distribution is established by the time the fluid reaches the downstream injection size. Solutes with low molecular weights require impractically high field strengths to form substantial gradients, whereas particulate density modifiers establish the gradient both rapidly and effectively. Ideally each particle type in SdHyFFF is focused into a very thin layer at its own characteristic elevation. Here it occupies a thin fluid layer flowing at a fixed velocity. The difference of SdHyFFF from the normal SdFFF is that it is the only FFF methodology for which each distinct species is narrowly confined to its own unique velocity state.

The applications of SdHyFFF include the fractionation of polystyrene latex and biological particles

(human and animal cells). With the introduction of denser particles its effective density range has been extended to silica, thus making the technique applicable to environmental particles. Another application of SdHyFFF technique is the fractionation of coal and limestone particles.

In general, the SdHyFFF method is applicable to larger particles than SdFFF, where (wall-induced) steric effects become important for particle sizes around 1 μm . The focusing of sample zones at locations removed from the wall in SdHyFFF has the advantage of eliminating interface-related nonidealities, such as sample adhesion and zone broadening caused by surface roughness.

Important developments include the so-called hyperlayer flow FFF, which has extended the applications to particles larger than 1 μm in diameter. Also, the introduction of various programming procedures has been of importance. A number of reports of the combined use of FIFFF and multi-angle laser light scattering (MALLS) instruments have also been published, illustrating the usefulness of this hyphenated technique in characterizing colloidal particles.

Potential Barrier FFF (PBFFF)

Potential barrier field-flow fractionation (PBFFF), developed by Karaiskakis, is a combination of potential barrier chromatography and FFF. Potential barrier chromatography can be applied to separate particles based on differences in size or in any of the physicochemical parameters involved in the potential energy of interaction between the particles and the packing of the chromatographic column. The particle size analysis of colloidal materials by PBFFF is based either on particle size differences or on Hamaker constant, surface potential and Debye-Huckel reciprocal differences. The method, which is based on the existence of a surmountable potential barrier between the colloidal particles and the FFF channel wall, is classified as an FFF method rather than a chromatographic method, because the selective interaction is experienced in one phase. Thus, by combining potential barrier chromatography with normal or steric FFF one could separate according to two mechanisms, one governed by the depth of the potential energy well for the different particles and the other determined by the interactive force between the particles and the external field. In its simplest form the

Figure 3 Fractionation of haematite-I ($\alpha\text{-Fe}_2\text{O}_3(\text{I})$) with nominal diameter 0.148 μm and haematite-II ($\alpha\text{-Fe}_2\text{O}_3(\text{II})$) with nominal diameter 0.248 μm) colloidal particles by the potential barrier SdFFF technique. The experimental conditions, except for those given in the scheme, were as follows: field strength 15.5 g ; flow rate 150 $\text{cm}^3 \text{h}^{-1}$; void volume of the channel 2.06 cm^3 . Reproduced from Koliadima A and Karaiskakis G (1990) Potential-barrier field-flow fractionation, a versatile new separation method. *Journal of Chromatography* 517: 345, with permission from Elsevier Science.

technique consists of changing the ionic strength of the carrier solution from a high value, where only one of the colloidal materials of the binary mixture to be separated totally adheres at the beginning of the FFF channel wall, to a lower value, where all the adhered particles are released.

Figure 3 shows the fractionation of two haematite samples (α -Fe₂O₃(I) with nominal particle diameter 0.148 μ m and α -Fe₂O₃(II) with nominal particle diameter 0.248 μ m) with monodisperse spherical particles, by the PBSdFFF technique. The mixture was introduced into the channel with a carrier solution containing 0.5% v/v detergent FL-70, 0.02% w/w NaN₃ and 3×10^{-2} mol L⁻¹ KNO₃. At this high electrolyte concentration all of the α -Fe₂O₃(II) particles adhered at the beginning of the SdFFF Hastelloy-C channel wall, whereas all of the α -Fe₂O₃(I) particles were eluted from the channel. The average diameter of the eluted α -Fe₂O₃(I) particles was found from eqn [3] to be 0.151 μ m, in good agreement with that obtained by normal SdFFF (0.145 μ m) or determined by TEM (0.148 μ m). Variation of the carrier solution to one containing only 0.5% v/v detergent FL-70 and 0.02% w/w NaN₃ without any KNO₃ released all the adhered α -Fe₂O₃(II) particles and gave a particle diameter (0.244 μ m) in good agreement with that found by normal SdFFF (0.237 μ m) or obtained by TEM (0.248 μ m).

A general methodology for the analysis of a colloidal mixture by PB SdFFF consists of injecting into the column the mixture with a carrier solution in which the ionic strength is too high to ensure total adhesion of all the components of the mixture, except for one with the lower attractive force with the channel wall. Then a programmed variation (decrease) of the ionic strength of the carrier solution is applied to release, in time, the adherent particles according to their size and/or surface characteristics. As the PBSdFFF technique is based on particle-wall interactions, its applications can be extended by using different materials, such as stainless steel, Teflon and polyimide. PBSdFFF is also a convenient and accurate method for the concentration and analysis of dilute colloidal samples. This makes PBSdFFF a highly attractive technique for the characterization of samples where even particles of the same size but of different chemical composition are present in low concentration.

Future Developments

From the detailed description of the FFF techniques presented above, it is concluded that the most usable FFF methods for particle size analysis of colloids are SdFFF and FIFFF. Looking to the future, it

is reasonable to expect serious efforts by the companies producing FFF equipments, to improve their resolution and expand the particle size range to lower limits of analysis. As far as FFF applications are concerned, it is believed that future efforts will be focused on the size separation and characterization of polydisperse, irregular colloidal particles, as well as on the aggregation and deposition phenomena of colloids on solid surfaces.

COMPUTER DATABASES FOR TWO-DIMENSIONAL ELECTROPHORESIS

T. Toda, Tokyo Metropolitan Institute of Gerontology,
Tokyo, Japan

Copyright © 2000 Academic Press

Two-dimensional (2-D) electrophoresis is an unrivalled technique of the highest capacity to separate many thousands of proteins in complex specimens such as a crude extract of cells. The development of computer systems for 2-D gel image analysis has promoted the construction of comprehensive databases for 2-D electrophoresis. The recent advance in the Internet computer network has allowed us to share useful pieces of information located in many 2-D electrophoresis databases on the worldwide web (WWW) via the Internet. And a new field of research named proteomics has been growing based on 2-D electrophoresis databases.

2-D Electrophoresis

2-D electrophoresis, established by O'Farrell in 1975, is a combined technique of isoelectric focusing (IEF) and sodium dodecyl sulfate (SDS)-polyacrylamide gel electrophoresis (PAGE) for achieving the finest resolution of proteins in crude specimens. Protein molecules of different isoelectric points (pI) are separated at the first stage of IEF, and components of different molecular masses are resolved in the second-dimensional SDS-PAGE.

The IEF in a mobile pH gradient, which is automatically generated by lining up carrier ampholytes in the order of pI, is performed in the original protocol of O'Farrell's 2-D electrophoresis. However, there is still a problem with the conventional IEF method in the drift of the pH gradient toward the cathode. Righetti and colleagues have devised an improved method of IEF which runs on an immobilized pH gradient (IPG) to prevent cathodic drift. The IPG-IEF is adopted in most current protocols of 2-D electrophoresis for constructing computer databases.

Protein Detection

Proteins separated on a gel plate are detected by autoradiography if they are labelled with a radioisotope. Nonradioactive proteins are visualized by silver or dye staining depending on the protein amount on

the gel. The protein profile on the 2-D gel reports useful information about qualitative and quantitative states of proteins in the specimen. Most computer databases for 2-D electrophoresis have generally been constructed on such visualized 2-D gel images.

2-D Gel Image Analysis

Computer analysis of the 2-D gel images was developed after O'Farrell's paper because 2-D gel images were too complicated to be analysed manually. Lipkin and Lemkin of the National Institutes of Health in the USA made their GELLAB system on a DEC minicomputer in 1980, and independently of this, Anderson *et al.* constructed their original TYCHO system in 1981. Garrels and Franza prepared a prototype software for 2-D gel image analysis on a compact Hewlett Packard desktop computer in 1979, and then developed it into the QUEST system for an UNIX-based minicomputer in 1983. The PDQUEST, which is a commercially available software package for SUN UNIX workstations, was a revision of the QUEST system. Many other software packages, such as Melanie II and GELLAB II, have been made commercially available. Those Macintosh- and Windows-based software packages have allowed 2-D gel image analysis to be performed easily for database construction.

Western Blotting

Western blotting is an immunochemical technique for detecting specific proteins. Protein spots separated by 2-D electrophoresis are transferred on to a nitrocellulose or polyvinylidene difluoride (PVDF) membrane by electrotransfer blotting. After blocking, the membranes are treated with a specific antibody and followed by a second enzyme-linked antibody. Localization of specific protein on the membrane is visualized by an enzyme reaction. The results of spot protein identification by Western blotting are also included in 2-D electrophoresis databases.

Microsequencing

The N-terminal peptide sequences of proteins are directly determined with an automatic peptide sequencer after electrotransfer blotting on to a PVDF membrane, if the N-terminal α -amino group is free.

Proteins that are blocked at the N-terminus are often cleaved with endopeptidase. The digests are separated by reversed-phase high performance liquid chromatography (HPLC) and then subjected to sequencing. Protein databases on the Internet may answer a query on the homology of the amino acid sequence for identification of the protein if the database includes an entry of the protein itself or family gene products. The sequence data and the results of homology search are both valuable information for constructing 2-D electrophoresis databases.

Mass Spectrometry

Mass spectrometry is another powerful technique for identification of proteins separated by 2-D electrophoresis. The peptide mass fingerprinting of endopeptidase digests is extensively used for primary assignment of the protein. The ExPASy Molecular Biology server (<http://www.expasy.ch/>) offers useful proteomic tools such as PeptIdent, which helps us in peptide mass fingerprinting works for protein identification (Figure 1).

Peptide Mass Fingerprinting

Name of the unknown protein: new

Database: new

Note: For proteins from TrEMBL, peptides with masses >10000 Da have not been indexed.

pI: within pI range:

Mw: within Mw range (in percent):

Species to be searched:

Note: As of SWISS-PROT release 37, OC (Organism Classification) lines contain the classification terms proposed by the NCBI.

Enter a list of peptide masses (separated by spaces or newlines) that correspond to the unknown protein:

Or upload a file in .pkm format from your computer (only works if you see a 'browse' button next to the text entry field, e.g. for Netscape browsers resp. Internet Explorer 4). The peptide masses will be extracted automatically from this file:

All peptide masses are

- ☒ [M+H]⁺ or ☐ [M], and
- ☒ monoisotopic or ☐ average.

The peptide masses are with cysteines treated with:

- ☐ with acrylamide adducts on cysteines
- ☐ with methionines oxidized.

Mass tolerance:

Enzyme:

Allow for missed cleavage sites (MC).

Report only proteins with at least peptide hits.

Display a maximum of matching proteins.

History of 2-D Electrophoresis Databases

The 2-D electrophoresis database, reported by Lipkin and Lemkin in 1980, was only for multiple 2-D gel image analyses on a stand-alone minicomputer. In their GELLAB system, a composite gel (CGEL) database was made by extracting spot data from multiple gels and merging them into a representative gel. The primary database consisted of the lists of corresponding spots, their associated properties and interrelations. The human serum protein 2-D electrophoresis database for clinical use, reported by

Anderson and his co-workers in 1981, was also only for personal use on an offline computer. Human keratinocyte 2-D electrophoresis databases, made by Celis *et al.* on a UNIX workstation with PDQUEST software, were offered to many research groups commercially, but not made accessible on the Internet.

Appel and his co-workers constructed their SWISS-2DPAGE database (Figure 2) on the ExPASy molecular biology server of the Swiss Geneva University Hospital in 1993. It was the first regular 2-D electrophoresis database on the WWW, and it has been accessible on the Internet.

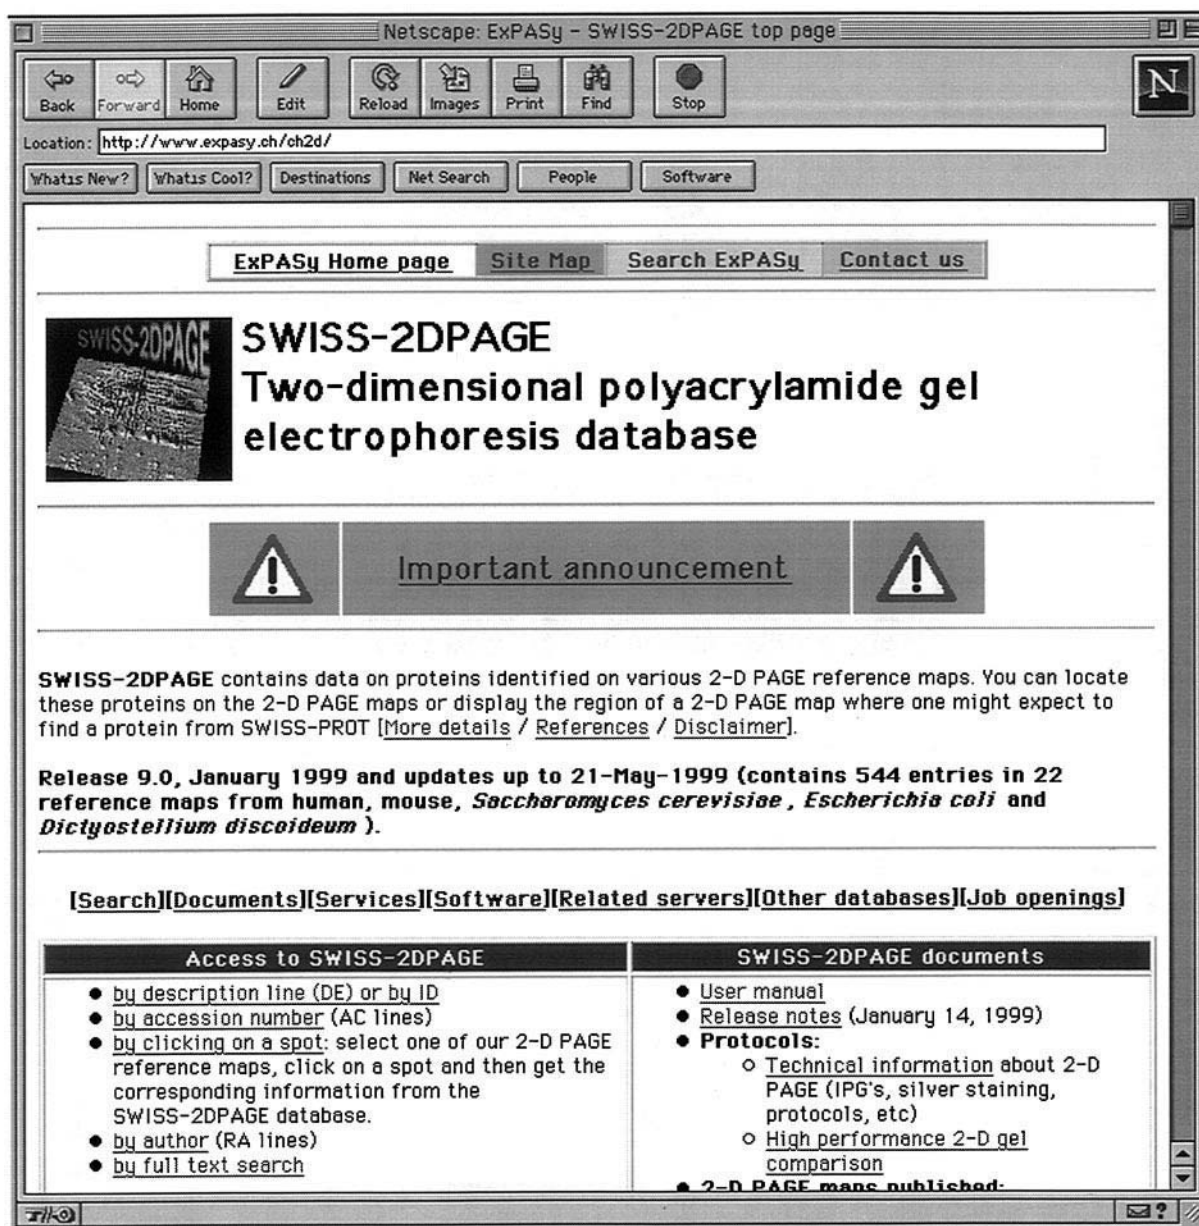

Figure 2 The SWISS-2DPAGE top page in the ExPASy Molecular Biology server of the Swiss Geneva University Hospital. The URL is <http://www.expasy.ch/ch2d/>.

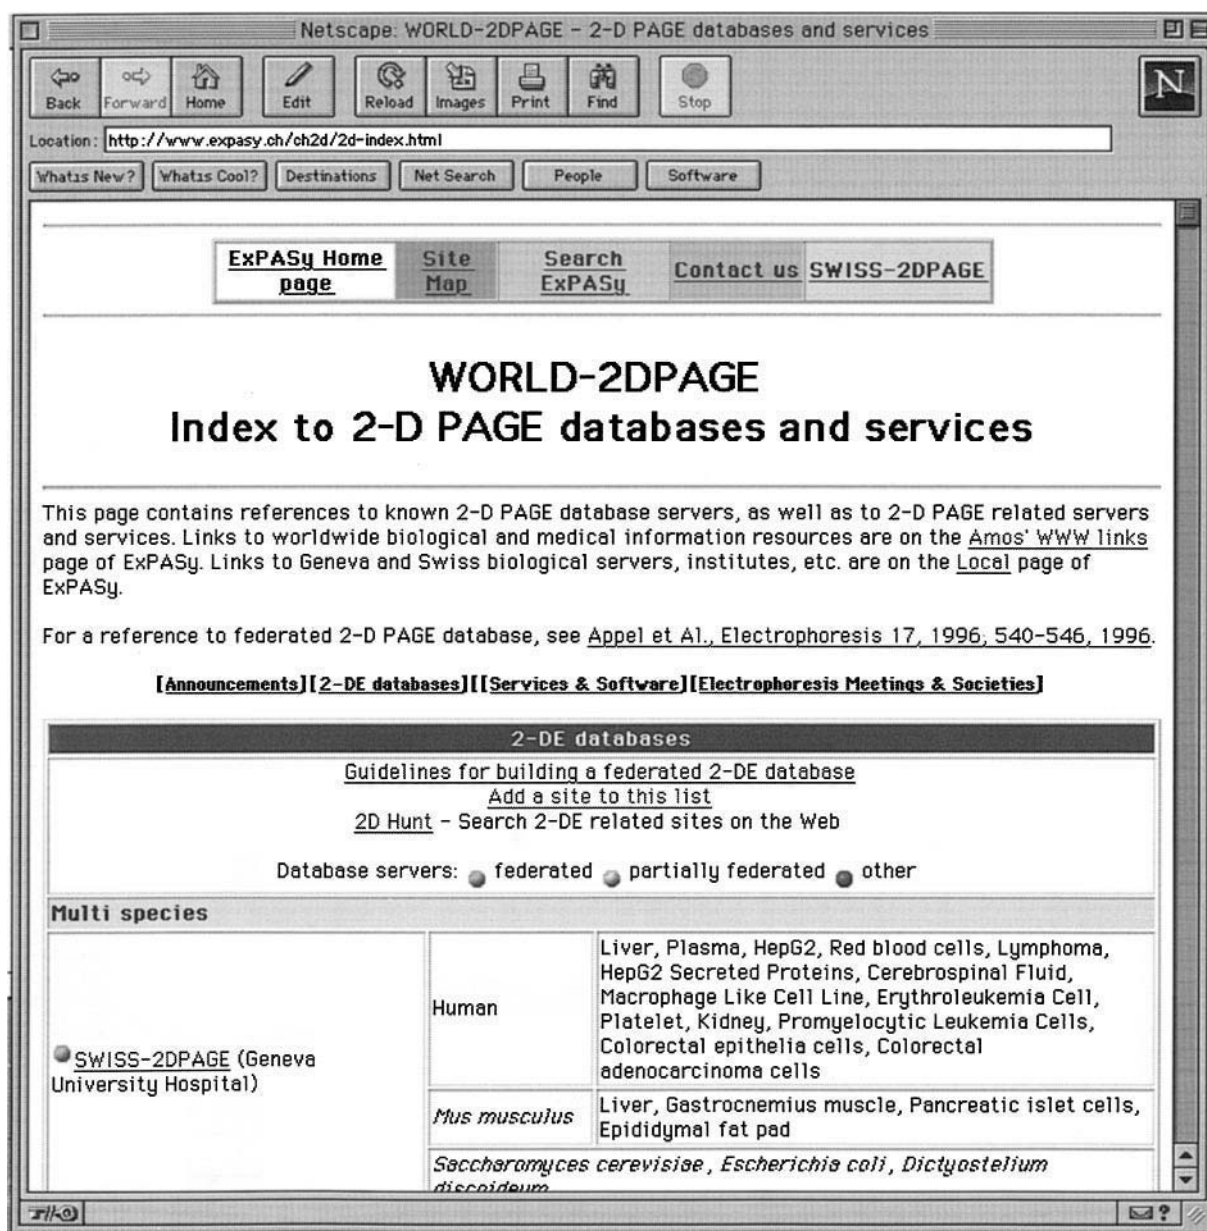

Figure 3 The WORLD-2DPAGE home page for indexing to 2-D PAGE databases and services throughout the world. The URL is <http://www.expasy.ch/ch2d/2d-index.html>.

WORLD-2DPAGE home page (Figure 3) presented at <http://www.expasy.ch/ch2d/2d-index.html> in the ExPASy server offers a convenient link to many 2-DE databases in the world.

The databases listed in Table 1 were indexed in the WORLD-2DPAGE page for link as of 15 June, 1999.

Some of the databases have been built following the guidelines for the federated 2-D electrophoresis database recommended by Appel *et al.* Rules for the database federation are summarized in Table 2.

World-Wide Web for 2-D Electrophoresis Database

The WWW is a database server system which was initiated in the European Centre for Nuclear Research on the basis of Internet protocol technology. The WWW allows browsers on a computer to access information stored on remote servers through the Internet. One of the main features of WWW documents is the hypertext structure; another significant feature is the function of a clickable image map.

Hypertext Cross-Reference

Links from the 2-D electrophoresis database to related databases, such as GenBank DNA database in NCBI Entrez, SWISS-PROT protein database or SWISS-3DIMAGE three-dimensional structure databases, through hypertext cross-references is a common function of most databases for 2-D electrophoresis. The function is achieved with anchor tags in hypertext mark-up language (HTML) and executive scripts for common gateway interface (CGI). For example, in TMIG-2DPAGE, the data entry for human nm-23 carries the following hypertext cross-reference to the corresponding SWISS-PROT (P15531) and NCBI GenBank (X75598) entries respectively.

SWISS-PROT

```
<A HREF = "http://www.expasy.ch/cgi-bin/
sprot-search-ac?P15531" TARGET = "_blank">
P15531 </A>
```

Table 2 Guidelines for building a federated 2-DE database

1. Individual entries in the database must be accessible from remote by keyword search
2. The database must be linked to other databases through active hypertext cross-references
3. A main index has to be supplied that provides a means of querying all databases through one unique entry point
4. Individual protein entries must be accessible through clickable images
5. 2-DE analysis software, been designed for use with federated 2-DE database, must be able to access directly individual entries in any federated 2-DE database

For full details, see Appel RD *et al.* (1996) in *Electrophoresis* 17: 540–546.

GenBank

```
<A HREF = "http://www3.ncbi.nlm.nih.gov/
htbin-post/Entrez/ query?db = n&form =
6&dopt = g&uid = X75598" TARGET =
"_blank"> X75598 </A>
```

Clickable Image Map

Clickable image map is a function of CGI installed in the WWW server software for achieving an active link from a location on an image to a corresponding file. All federated 2-D electrophoresis databases on the WWW have 2-D gel images for the clickable image map. The content of each protein data entry is displayed on the monitor screen when the mouse button is clicked on the corresponding spot on the 2-D gel image.

Setting up a 2-D Electrophoresis Database on the WWW

To set up a 2-D electrophoresis database, software for WWW server, such as Apache httpd, must be working on a UNIX or LINUX server computer connected to the Internet. The function of clickable image map is included in the Apache modules if they are properly installed. To set up a new 2-D electrophoresis database, prepare the following four types of files first, according to the *Apache Reference Manual*, which is available in the Apache directory.

1. A hypertext file for the image map top page (*.html).
2. A 2-D gel image file in the GIF format for the clickable image map (*.gif).

3. A map file for directing the jumping destination (***.map).
4. Text files of protein data entries as destinations for links (***.html).

When these files are placed in the appropriate directories in the WWW server, the basal activity of the 2-D electrophoresis database starts running.

2-D Electrophoresis Databases on the WWW

SWISS-2DPAGE

The SWISS-2DPAGE is a fully implemented 2-DE federated database. The ExPASy WWW server is

home to five locally maintained databases (SWISS-PROT, SWISS-2DPAGE, PROSITE, SWISS-3DIMAGE and ENZYME). Besides the database service, the server offers special tools for proteomic analysis, such as PeptIdent for peptide mass fingerprinting. SWISS-PROT serves as a searchable main index, prepared according to rule 3, and has cross-references to the other four databases. SWISS-2DPAGE contains data on protein identified on various 2-D PAGE reference maps. The hypertext cross-references as of 15 June 1999 include links to SWISS-PROT, YPD database of yeast *Saccharomyces* and the ECO2DBASE *E. coli* database. The X-ray crystallography Protein Data Bank (PDB), the Mendelian Inheritance in Man data bank (OMIM), the G-protein-coupled receptor database (GCRDb) and the

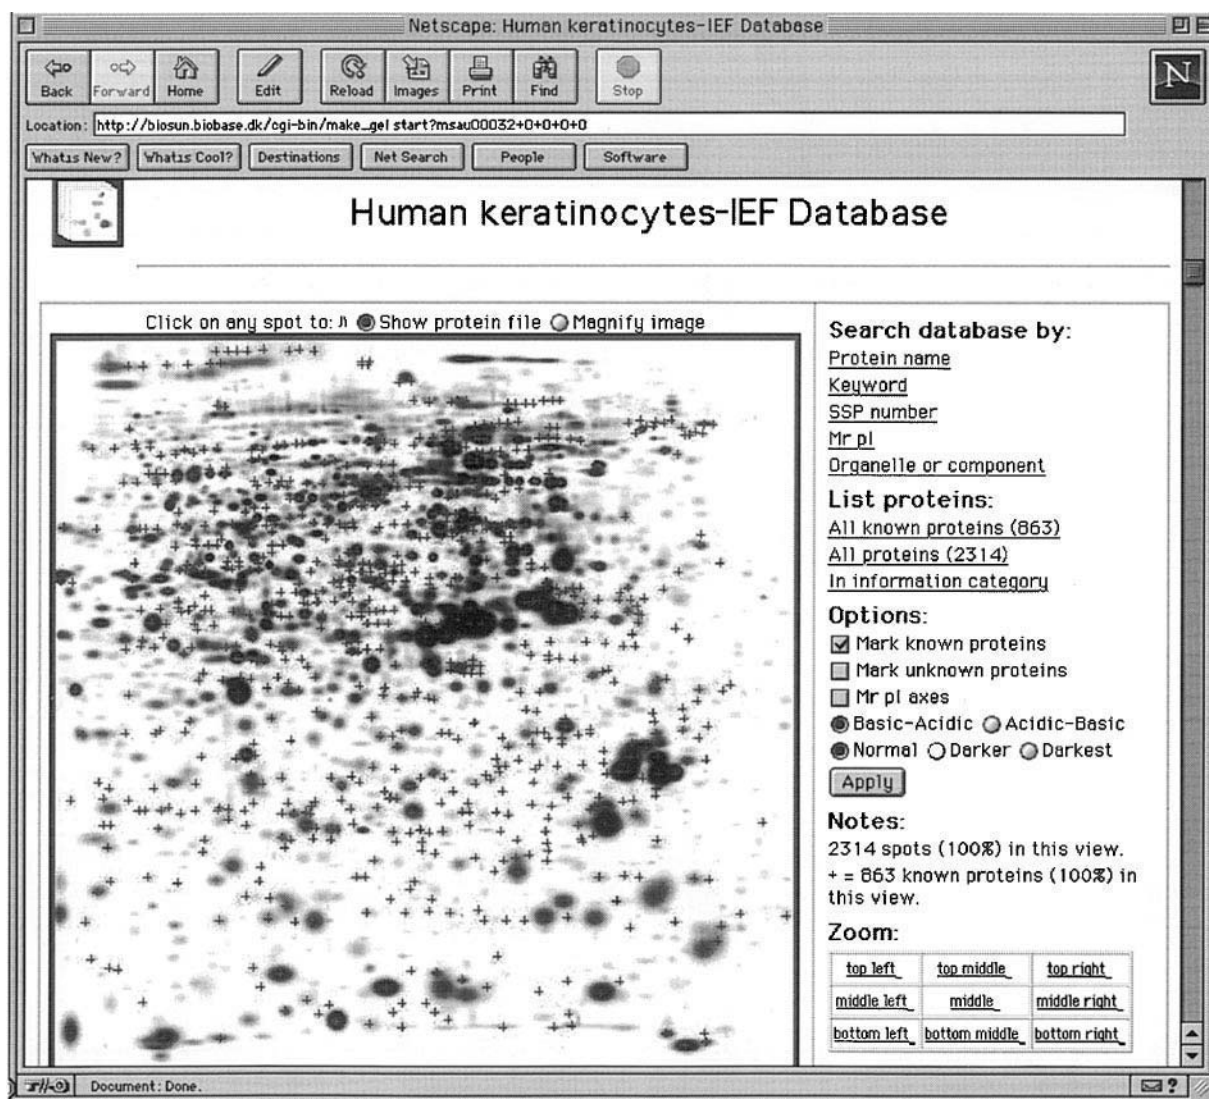

Figure 4 Human keratinocytes 2-D PAGE database in the Danish Centre for Human Genome Research. The URL is http://biosun.biobase.dk/cgi-bin/make_gel.start?msau00032+0+0+0+0.

database of yeast (*Saccharomyces cerevisiae*) genes coding for proteins (LISTA) are also linked through SWISS-PROT.

Human 2-D PAGE Databases of the Danish Centre For Human Genome Research

The human 2-D PAGE databases at the University of Aarhus, which were developed for functional genome analysis in health and disease, contain data on pro-

teins identified on various reference maps. Databases of human keratinocytes (Figure 4) are served for the study of skin biology, and those of transitional cell carcinomas are for the study of bladder cancer.

Heart-2DPAGE

The Heart-2DPAGE at the German Heart Institute in Berlin is a human myocardial 2-D protein database that implements the first four rules of the

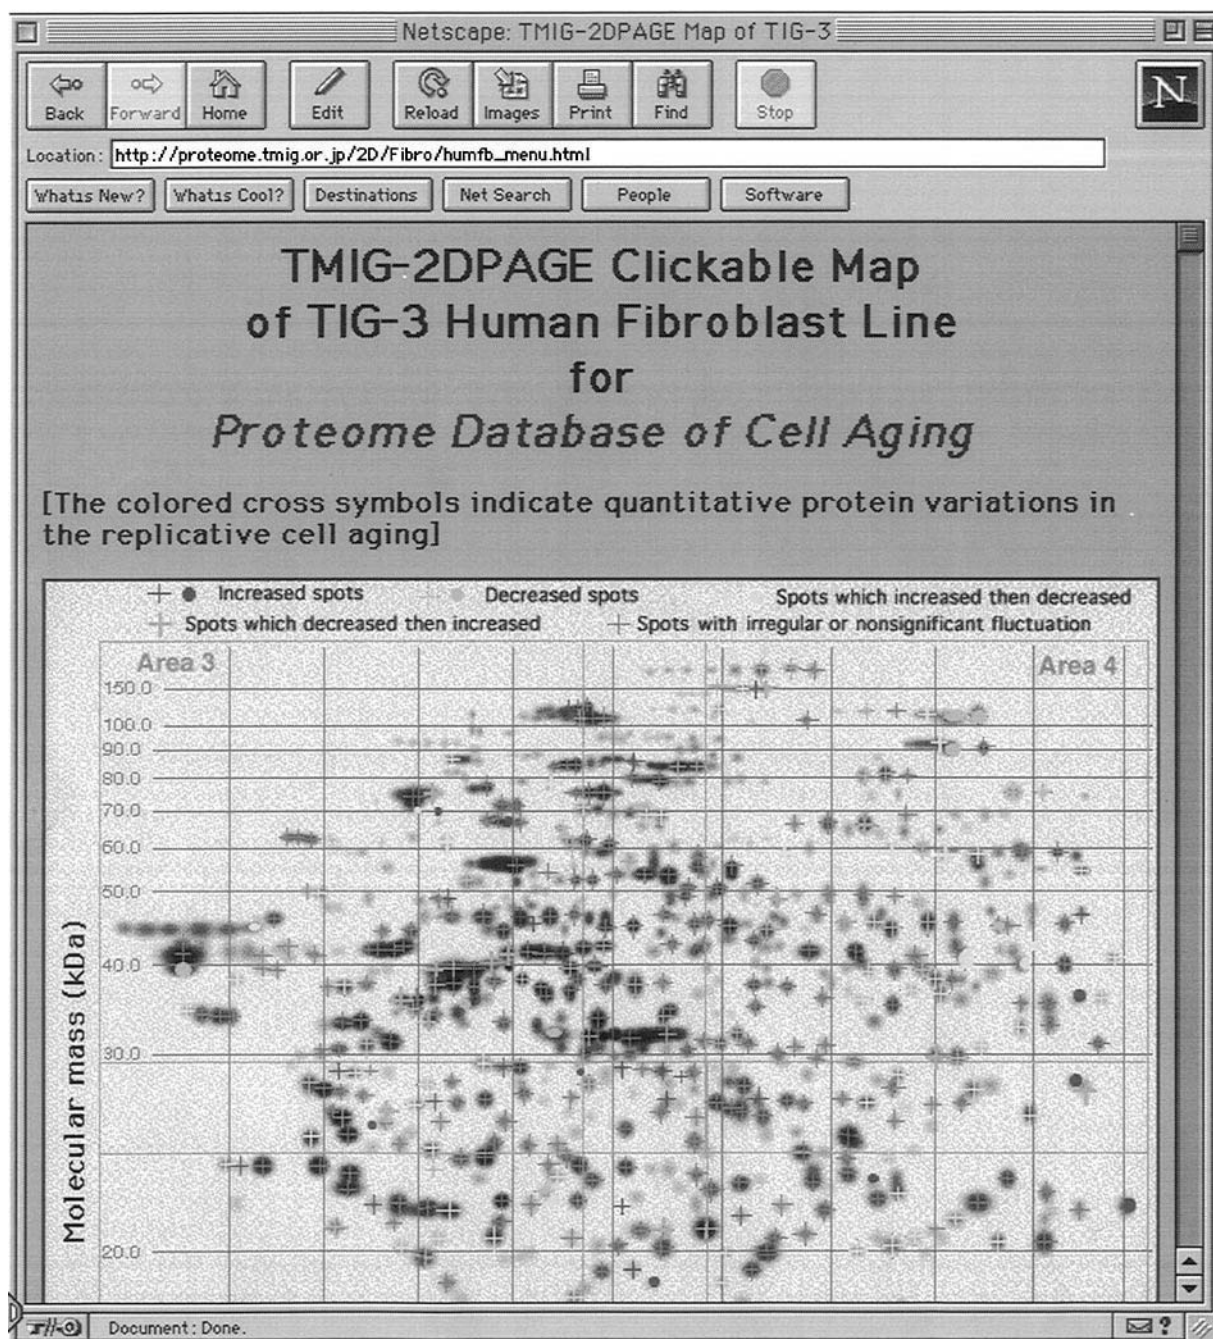

Figure 5 TMIG-2DPAGE clickable map of TIG-3 human fibroblast line. The URL is http://proteome.tmig.or.jp/2D/Fibro/humfb_menu.html.

federated 2-D database. It contains data on the human heart ventricle and atrium. The data are accessible both by keyword search on the protein name and by mouse-clicking on two images of 2-D. Entries provide data related to the isoelectric point, the molecular mass and the amino acid sequence of each spot protein.

PDD Protein Disease Database

The PDD Protein Disease Database on the WWW server is a part of the National Institute of Mental Health and National Cancer Institute (NIMH-NCI) Protein-Disease Database Project for correlating diseases with proteins observed in serum, cerebrospinal fluid, urine and other common human body fluids based on biomedical literature. The PDD database includes the data of quantitative and qualitative protein variations with disease states, answering questions on protein patterns found in common body fluids with respect to disease conditions in the literature.

TMIG-2DPAGE

TMIG-2DPAGE is a database of human proteins involved in the mechanisms of cell ageing. It includes two clickable image maps for data entries of proteins in normal cell ageing, and for those in the disease state of Werner's syndrome patients. On the TMIG-2DPAGE clickable map of TIG-3 human fibroblast line, quantitative variations of proteins observed in the process of replicative cell ageing are demonstrated with coloured crosses (Figure 5).

As a mouse button is clicked on a protein spot, the corresponding data entry is displayed on the browser. Each data entry contains information on age-related protein variation, physicochemical properties, references and active links to both SWISS-PROT and NCBI Entrez nucleotide sequence databases.

Keyword Search of 2-D Electrophoresis Databases

The 2DHunt on the ExPASy server (<http://www.expasy.ch/ch2d/2DHunt/>) is a convenient search engine for WWW sites of 2-D electrophoresis databases. The site list for 2DHunt search is periodically created by the site retrieval robot supplied from the Marvin

(Multi-Agent Retrieval Vagabond on Information Networks). Although some irrelevant sites may sometimes be hit, the search engine is helpful for many researchers to find specific 2-D electrophoresis databases of their own interests.

This article is reproduced from *Encyclopedia of Analytical Science*, Copyright © 1995 Academic Press

Toiletries, used by millions of consumers for the daily care and hygiene of the body, include several products (mainly rinse products) with different formulae: soaps, shampoos, bath foams, toothpastes, deodorants.

Since surfactants are the basic materials used in toiletries (in soaps and shampoos they increase the washing properties of water; in shaving products they act as wetting and foaming agents; in bath oils they make the perfume water-soluble; in hair products they are used as conditioners), this article will deal with the techniques used for the analysis of these important constituents.

Leaving aside the rough, but still used, organoleptic testing (odour, colour, clarity, opalescence), analytical procedures for quality control may range from physical evaluations (specific gravity, refractive index, optical rotation, viscosity) to chemical analysis by standard volumetric and gravimetric methods, and instrumental analysis by chromatographic techniques (thin-layer, gas and liquid chromatography) and spectroscopic techniques (ultraviolet, infrared and nuclear magnetic resonance spectroscopy and mass spectrometry). Chromatographic and spectroscopic methods now find wide application, since toiletries and raw materials are complex mixtures, and there is a constant need to distinguish subtle structural differences in composition and determine impurities even if present in trace amounts.

The term surfactant (a contraction for surface-active agent) is used to describe organic chemicals that, when added to a liquid, change the interfacial properties of that liquid. Chemically surfactants can be divided into two major classes: nonionic

(uncharged substances) which do not dissociate in aqueous solution, and ionic (charged substances) which dissociate and form ions, one of which becomes the actual surface-active agent. Ionic surfactants are classified by the nature of their charges in solution: anionic (negatively charged), cationic (positively charged), amphoteric (both positively and negatively charged).

Anionic Surfactants

Anionic surfactants constitute about 65% of all surfactants manufactured and it is not surprising that the bulk of literature on surfactants deals with the analysis of these compounds. **Table 1** reports the main types of anionic surfactants used in toiletries.

The quality control of anionics in raw materials and in finished products is mainly quantitative and several methods that give a total estimate of active ingredients have been developed. The two-phase mixed indicator titration and other titrimetric analyses, such as direct colorimetric titration and precipitation titration are the simplest procedures, since they are sufficiently reliable, require little and inexpensive equipment, and can be used for both product development and quality control applications. The two-phase mixed indicator titration is based on the extraction of an anionic-indicator or cationic-indicator complex into a nonaqueous solvent (usually chloroform) in equilibrium with an aqueous solution of the unknown anionic surfactant or the titrating cationic surfactant. The method is not quantitative for compounds containing fewer than 12 carbon atoms when chloroform is the organic phase (in this case a mixed organic phase of 2:3 (v/v) chloroform-1-nitropropane must be used). Sodium, magnesium or sulfate ions at concentrations up to 0.4 mol L^{-1} do not interfere, while chloride interferes above $5 \times 10^{-3} \text{ mol L}^{-1}$.

All the spectrophotometric procedures are based on the formation of a solvent-extractable compound

Table 1 Anionic surfactants

Type	General structure
Alkyl carboxylates (soaps)	$R-COO^-X^+$ C_8-C_{18} fatty acids; salts with NaOH, KOH, NH_4OH , monoethanolamine (MEA), diethanolamine (DEA), triethanolamine (TEA)
Alkylethoxylated carboxylates	$R-(OCH_2CH_2)_nOCH_2COO^-X^+$ $R = C_8-C_{18}$ fatty alcohols $X = Na, K, NH_4, MEA, DEA, TEA$
Alkyl sulfates	$R-O-SO_3^-X^+$ $R = C_8-C_{18}$ fatty alcohols $X = Na, K, Mg, NH_4, MEA, DEA, TEA$
Alkylethoxylated sulfates (AES)	$R-(OCH_2CH_2)_n-O-SO_3^-X^+$ $R = C_8-C_{18}$ fatty alcohols $X = Na, K, Mg, NH_4, MEA, DEA, TEA$
Alkylarylsulfonates	$R-C_6H_5-SO_3^-X^+$ $R = C_{10}-C_{12}$
α -Olefin sulfonates	$R-SO_3^-Na^+$ $R = C_{14}-C_{16}$
Isethionates	$R-CO-O-CH_2CH_2-SO_3^-Na^+$ $R-CO = C_{12}-C_{18}$ fatty acids

between the anionic surfactant and a coloured cationic species: Methylene blue, Methyl green, Toluidine blue, Rosaniline, Brilliant green and Methyl violet being the most widely used. These cationic compounds are not extractable as such by organic solvents, but in the presence of anionic species they form a stable, stoichiometric ion-association complex that is poorly soluble in water, because it has no nett charge. The complex is extracted into the organic solvent and the absorbance gives a direct measure of the surfactant present.

These techniques are not suited for establishing the qualitative composition of these surfactants, e.g. for differentiating homologues and oligomers, for characterization of single components of a surfactant mixture, or for detection and quantification of impurities (unreacted materials, by-products), and when such determinations are required for finished detergent formulations.

Hence, more specific and sensitive chromatographic techniques such as thin-layer chromatography (TLC), gas chromatography (GC) and liquid chromatography (LC) have been developed and are now widely accepted in the surfactant industry. Mass spectrometry (MS) and tandem mass spectrometry (MS-MS), although considered the techniques of choice for rapid characterization of surfactant mixtures, have not yet gained general acceptance as routine analytical techniques.

TLC, because of its rapidity and low cost, is particularly useful. Anionics (sulfates, sulfonates, soaps) can easily be separated under the following conditions (all ratios given are volume ratios).

One-dimensional chromatography

Alumina 60 F254 with isopropanol.

Silica gel 60 with propanol-chloroform-methanol-10 mol L⁻¹ ammonia (10:10:5:2); ethylacetate-acetic acid-methanol-10 mol L⁻¹ ammonia (45:5:2.5); ethanol-acetic acid (9:1).

Silica gel G containing 10% ammonium sulfate with chloroform-methanol-0.05 mol L⁻¹ sulfuric acid (80:19:1).

Two-dimensional chromatography

Silica gel with acetone-tetrahydrofuran (9:1) followed by propanol-chloroform-methanol-10 mol L⁻¹ ammonia (10:10:5:2).

Several spray reagents are used for detection and identification: Pinakryptol Yellow, Dragendorff, ninhydrin, leucomalachite green and iodine vapour.

This method can be applied to all classes of tensides as it distinguishes anionics from nonionics (fatty diethanolamides and ethoxylates) in shampoos, bath foams and soaps. The aqueous samples can be freeze-dried and extracted with a suitable solvent (ethanol-water) to minimize foaming.

Basically, anionics are analysed by reversed-phase LC using an ion-pairing agent and an organic solvent (acetonitrile, methanol, tetrahydrofuran)-water gradient. In reversed-phase ion pair chromatography, the addition of an appropriate ion-pairing reagent (tetrabutylammonium hydrogensulfate) to the mobile phase suppresses the ionic nature of the sample while introducing some charge to the nonpolar surface of the stationary phase. The retention of the resulting

ion pair is then controlled by pH, counterion concentration and mobile phase polarity. Linear and branched-chain (C_4 – C_{18}) alkylbenzenesulfonates are separated by this method according to the length and structure of the alkyl chain, using as the mobile phase 0.1 mol L^{-1} tetrabutylammonium hydrogensulfate (pH 5)–water–acetonitrile (gradient elution). At pH 5, the sulfonates and pairing reagent are completely ionized, as are the carboxylated surfactants, whose pK_a values are somewhat higher ($pK_a \sim 4$). The structure and concentration of the pairing agent also influences the retention behaviour: increasing the lipophilicity increases the retention of the surfactant ion pair by enhancing its affinity for the nonpolar stationary phase. The increase in the concentration of the pairing agent will lead to greater coverage of the stationary phase surface and consequently to longer sample retention.

A limitation is that only the chromophoric components of such mixtures can be monitored by ultraviolet (UV) absorption detection. Nonchromophoric anionic surfactants such as alkyl sulfates or their corresponding alcohols and acids can be determined by LC after derivatization to 3,5-dinitrobenzoate esters or *p*-(methylthio)benzoate esters. The acidic forms of α -olefin sulfonates, alkyl sulfates, alkyl-ethoxylated sulfates and alkyl phosphates react with 4-diazomethyl-*N,N*-dimethylbenzenesulfonamide to produce UV-absorbing derivatives that can be separated by reversed-phase LC. Direct detection (no derivatization) can be achieved by the use of a spectrofluorimetric detector operating at 225 nm (excitation) and 295 nm (emission) (reversed-phase C_{18} (RP-18) column; mobile phase: 0.1 mol L^{-1} sodium perchlorate in 80:20 methanol–water) or by a differential refractometer (refractive index) detector. Long-chain alkane sulfonates (C_{12} – C_{20}) are separated by this method using a phenyl column with a 75% methanol–25% 0.1 mol L^{-1} sodium nitrate mobile phase.

An alternative approach to separating and detecting aliphatic anionic surfactants is ion interaction chromatography (reversed-phase column) with an aromatic ion-pairing agent also acting as chromophore for UV detection at 254 nm (cetylpyridinium chloride, phenethylammonium ion).

Anion exchange chromatography with indirect detection is not a common approach for aliphatic sulfonates, although it is simpler than ion pair chromatography. Using hydrogenphthalate, sulfosalicylic acid or *m*-sulfo benzoic acid in 60:40 acetonitrile–water as mobile phase, C_2 – C_8 sulfonates can be separated on a strong cation exchange column with indirect UV absorbance detection at 297, 320 and 298 nm, respectively. C_6 – C_{12} aliphatic sulfonates

and sulfates can also be analysed using sodium naphthalenedisulfonate–acetonitrile as the mobile phase on a polymeric fluorocarbon–amine cross-linked weak anion exchange silica column with either indirect conductivity or photometric detection modes.

The solid-phase reagent (SPR) procedure has been introduced recently as a new method of postcolumn conductivity detection of alkylsulfates and alkyl-sulfonates. SPR, an aqueous suspension of sub-micrometre particles of a polymeric cation exchange material in the hydrogen form, is pumped into the eluent stream coming from the column (silica-based reversed-phase). The postcolumn reaction transforms the tetrabutylammonium alkyl sulfate or sulfonate into the corresponding free acid. This changes the analytes into more conductive species and tetrabutylammonium borate eluent to the low conductivity boric acid. The conductivity detection method with SPR makes it possible to employ gradient elution for separation of complex mixtures.

GC and GC-MS cannot be applied directly to the analysis of anionic surfactants since these compounds are too polar and nonvolatile to be amenable either to GC or to conventional electron-impact MS (desulfonation with acids, alkali fusion sulfochlorination, methylation, pyrolysis-GC are well known methods of prederivatization for GC analysis). The use of soft ionization techniques such as field desorption (FD) and fast atom bombardment (FAB) is highly suited for characterization of these polar compounds by MS.

FAB-MS (in positive or negative ion mode) can be used to analyse complex anionic mixtures without prior separation of the components, since it gives abundant deprotonated (negative) or cationized (positive) molecular ions, and no fragmentation. As is shown in the case of a mixture of ethoxylated alcohol (C_{12}/C_{14}) sulfates (Figure 1), the technique not only gives the complete pattern of oligomer distribution (length of the alkyl and/or of the ethoxylate chain), but also information about the purity of the raw material (the c and d series in Figure 1B are the cationized molecular ions of unreacted materials, the unsulfated ethoxylated fatty alcohols). Ethoxylated alcohol sulfates are easily detected by this technique in finished detergent formulations, even in the presence of other surfactant types (i.e. amphoteric tensides), as has been demonstrated for shampoos.

Nonionic Surfactants

Nonionic surfactants constitute the second most important class of tensides: although their foaming properties are low in respect to those of anionics, they

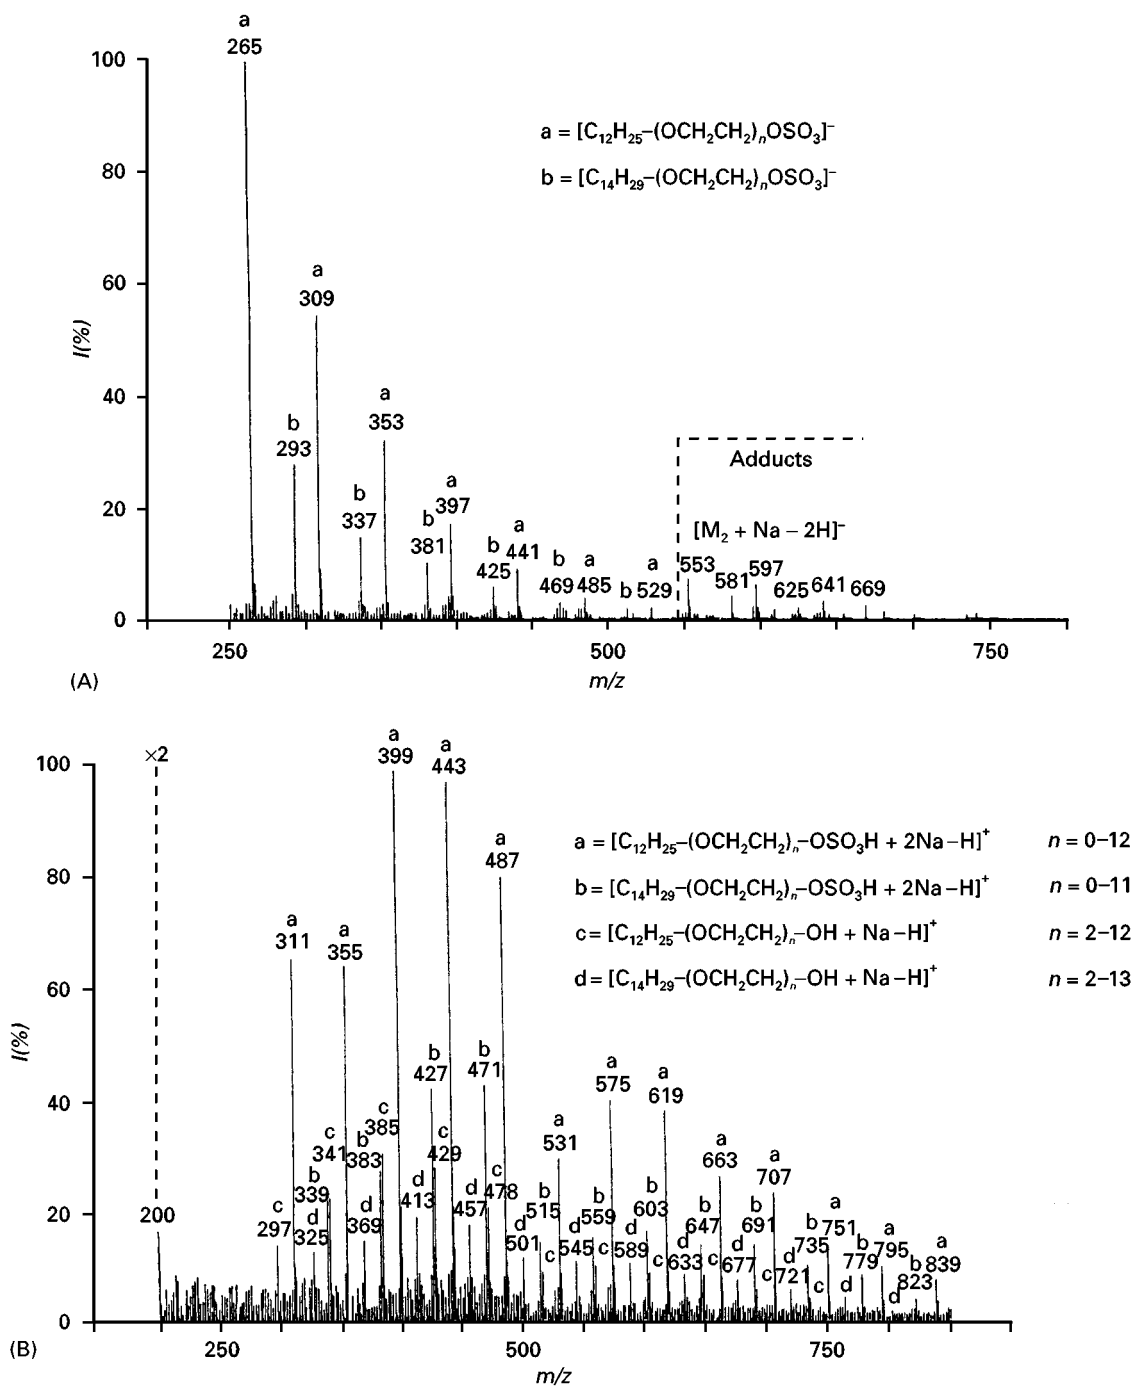

Figure 1 (A) Negative-ion and (B) positive-ion FAB mass spectra of ethoxylated alcohol sulfates (anionic surfactants). (From Maffei Facino *et al.*, 1989.)

are widely used in detergent formulations (especially in bath foams) to increase viscosity and as foam boosters. Table 2 reports the chemical classification of the most important nonionic surfactants.

Spectrophotometric methods for the quantitative analysis of nonionic surfactants are popular: they are based on complex formation with tungstophosphoric

acid, molybdophosphoric acid, picric acid, Malachite green, potassium tetracyanatozincate and ammonium tetrathiocyanatocobaltate (III). This last reagent gives better results than tungstophosphoric acid and than the potentiometric method with Dragendorff's reagent. It can be applied for determination of ethoxylate compounds in detergent solutions: the sur-

Table 2 Nonionic surfactants

Type	General structure
Ethoxylated alcohols	$R-O(CH_2CH_2O)_nH$ Reaction product between ethylene oxide and fatty alcohols
Ethoxylated alkylphenols	$R-C_6H_4-O(CH_2CH_2O)_nH$ Reaction product between ethylene oxide and alkylphenol ($R = C_8/C_9$)
Alkanolamides	$R-CO-N-(CH_2CH_2OH)_n$ $n = 1, 2$ Reaction product of fatty acids ($C_{10}-C_{18}$) with mono- or diethanolamine
Alkylglycosides (glucose ethers)	$R-O-(Gluc)_n$ Reaction product between glucose and fatty alcohols ($R = C_8-C_{14}$)

factant is extracted from the aqueous solution with chloroform and the extract is treated with the reagent to form a blue complex that is then analysed spectrophotometrically. The absorbance is not affected by temperature, electrolytes or dilution.

Several electrochemical and potentiometric techniques are also available for quantitative analysis of nonionic tensides: for example, using a barium ion selective electrode it is possible directly to quantitate the surfactant in the range of 2×10^{-5} to 1×10^{-3} mol L⁻¹. A typical potentiometric titration is based on formation of insoluble complexes with molybdophosphoric acid: the sample dissolved in aqueous ethanol containing barium chloride is treated with an excess of the complexant and the unreacted molybdophosphoric acid is titrated potentiometrically with diantipyrylmethane, using a platinum indicator cathode.

In the quality control of ethoxylated compounds, it is important to determine their composition, since they are manufactured as mixtures of homologous compounds that differ in the length of the ethoxylate and/or the alkyl chain. Several spectroscopic nuclear magnetic resonance (NMR) and infrared (IR) and chromatographic techniques (TLC, GC, LC) and supercritical fluid chromatography (SFC) are available to determine the degree of ethoxylation and the distribution of homologues in nonionic surfactant mixtures.

Both IR spectroscopy and NMR spectroscopy may be used for the determination of the average molecular mass (M_r), the average degree of condensation (x), and the hydrophilic/lipophilic balance (HLB) of nonylphenol ethylene oxide condensates. The IR method is based on the regression between the logarithm of the surfactant properties and the logarithm of the ratio of the heights of the bands at 840 and 960 cm⁻¹, corresponding to aromatic C-H vibrations: the first band is greater than the second for compounds of smaller degree of condensation, but this relationship becomes inverted as the degree of polymerization increases.

The NMR approach involves the calculation of absolute integrals of three types of hydrogen atoms: from these integration values it is possible to calculate the degree of condensation and the alkyl residue composition, as each surfactant molecule contains four aromatic hydrogen atoms that can be used as an internal reference to determine the number of hydrogen atoms corresponding to the remainder of the peaks.

TLC with a flame ionization detector (FID) has been applied for the separation and quantitative determination of nonionic surfactants containing an average number of oxyethylene units not higher than 8.0. The oligomers are separated on Chromarod S-II (silica gel-coated rods) with double development; (a) benzene-ethyl acetate (6:4) for 10 cm from the start; (b) ethyl acetate-acetic acid-water (8:1:1) up to a distance of 8 cm. After development, the rods are passed through a FID operating with hydrogen (160 mL min⁻¹) and air (2 L min⁻¹). The major advantage of LC in the analysis of nonionic surfactants lies in its ability to separate and quantitate alcohol or alkylphenol ethoxylate oligomers that differ in the length of the ethoxylate chain. While alkylphenol ethoxylates can readily be identified by UV detection, aliphatic compounds, since they do not possess significant UV absorption, must be derivatized prior to LC (for example by esterification with 3,5-dinitrobenzoyl chloride). Reversed-phase LC with refractive index detection has been proposed to establish the retention behaviour of a wide range of ethoxylated and/or propoxylated adducts: there is a linear relationship between the logarithm of the capacity factor and the degree of polymerization of the ethoxylated and/or propoxylated C₁₂, C₁₆, C₁₈ alcohols, ethylene oxide-propylene oxide copolymers, poly(ethylene glycol)s and poly(propylene glycol)s. This can be used not only for the prediction of chromatographic separation, but also for the estimation of the degree of polymerization and of the length of the alkyl chain.

Recently, the evaporative light-scattering (ELS) detector, also known as the mass detector, was

introduced as a universal detector for separation and quantification of all surfactant species. The detector measures light refracted by the nonvolatile particles after the effluent from the LC is nebulized and the carrier solvent is evaporated. The detector gives an equal and linear response factor for each class of surfactant that is independent of molecular mass (the amount of refracted light is proportional to the concentration of the analyte species).

Alcohol ethoxylates have been characterized by GC as acetate derivatives on a packed column or as silylated derivatives using a fused silica capillary column. However GC gives only a partial fingerprint, since only low molecular mass components can be detected (the free alcohols and short-chain ethoxylated homologues, up to approximately 12 ethylene oxide oligomers).

High temperature capillary gas chromatography and SFC are new alternative procedures for the analysis of these compounds that are thermally unstable or have low volatility. The alcohol and ethoxylate distributions, mean molecular mass and average number of moles of ethylene oxide can be calculated rapidly with both the methods (polyglycols with average molecular masses of 2000–2500 Da have been successfully analysed by SFC). Advantages and limitations of the SFC and high temperature capillary GC procedures can be summarized as follows: (1) for routine quality control analyses of known alcohol ethoxylates, both techniques appear to be equally suited; (2) SFC is time-saving because derivatization is not required, although for complex mixtures derivatization improves resolution (acetylation by means of acetic anhydride and pyridine or silylation with bis(trimethylsilyl)trifluoroacetamide and pyridine); (3) the GC technique is able to resolve C_{12} – C_{18} alcohol ethoxylate oligomers, thus avoiding ambiguous identification of components. Figure 2 shows the chromatographic profiles of a C_{12}/C_{13} alcohol ethoxylate with an average of 6.6 moles of ethylene oxide obtained by SFC and by high temperature capillary GC after silylation.

Among the mass spectrometric methods, the use of conventional GC-MS electron impact (EI) ionization is limited to nonionic surfactants with a low degree of ethoxylation. Compounds with a high degree of ethoxylation (20–25 units) can be identified directly in raw materials and in finished detergent formulations by soft ionization techniques such as direct chemical ionization (DCI), FD and FAB. This last, in positive ion mode, furnishes the complete pattern of oligomer distribution of ethoxylated compounds, since it gives a series of ions at 44-Da intervals (protonated and/or cationized molecular ions only, with no fragmentation). In addition FAB-MS (in positive or

Figure 2 Analysis of ethoxylated alcohols (nonionic surfactants) by GC, high temperature GC and SFC. (A) Capillary GC of a silylated C_{12}/C_{13} alcohol ethoxylate with an average of 6.6 moles of ethylene oxide. (B) Capillary SFC of the same mixture (un-derivatized). (C) Capillary high temperature GC of the same mixture (after silylation). (From Silver AH and Kalinoski HT (1992) *Journal of the American Oil Chemist's Society* 67: 599–608.)

negative ion mode) gives direct characterization of alkylpolyglycosides, a new generation of highly polar nonionic tensides not amenable to analysis by conventional chromatographic methods. The method, which is based on unambiguous molecular mass determination of the single components (protonated or deprotonated molecular ions), allows the definition of length of both the alkyl and the glucosidic chains (up to 10 glucose units).

Free poly(ethylene glycol)s (PEGs) are the main contaminants of ethoxylated derivatives and are frequently found in the products obtained from them, because they can be formed as side-products in the reaction of ethylene oxide with the hydrophobic component (in which case they are present as a mixture of homologous polymeric derivatives with a molecular mass distribution that depends on the reaction conditions); they can be added intentionally to obtain specific performances of the final product; and they can arise from the decomposition of adducts in the synthetic reaction or during the processing. Hence determination of free PEGs is important not only from the viewpoint of routine quality control of the manufacturing process, but also for the determination of the suitability of surfactants for specific purposes. Among the procedures used for the separation of PEGs from adducts and the unreacted starting material, a simple method involves extraction of an ethyl acetate solution of surfactants with 5 mol L⁻¹ sodium chloride, followed by extraction of the aqueous phase with chloroform, evaporation of the solvent and gravimetric determination of PEGs (accurate temperature control is required).

Column LC is faster and more reproducible for the separation of free PEGs from the other components of the mixture. Silica, hydrophobized with dichlorodimethylsilane, with chlorobenzene as the stationary phase, separates PEGs from their adducts using acetone–water–acetic acid as the mobile phase. Utilizing reversed-phase chromatography on silanized silica gel, and 30% aqueous isopropanol as mobile phase, PEGs are eluted, while adducts are desorbed with 96% ethanol. Partition chromatography, with ethyl acetate as the mobile phase and cellulose as support for the stationary phase (30% sodium chloride solution), is used for the determination of PEGs in adducts of fatty alcohols, alkylphenols, fatty acids and alkanolamides.

By applying hexane–isopropanol–water mobile phases of controlled composition (different ratios of hexane to isopropanol), either ethylene oxide adduct (EOA) or PEG oligomers can be separated on a bonded diol phase, and their distributions evaluated (refractive index detection). The PEG or EOA oligomers can easily be separated up to the 30-mer even without gradient elution, and ethoxylated surfactants (fatty alcohols, fatty acids, fatty acid monoethanolamides and alkylphenols) up to an ethoxylation degree of 20.

Another important contaminant of ethoxylated derivatives (both anionic and nonionic) is 1,4-dioxane: according to the European Economic Community Directive on Cosmetics, commercial products must be free from this compound, since it is carcinogenic in

rats and mice. 1,4-Dioxane is formed by dimerization of ethylene oxide during the process of alcohol/phenol ethoxylation and might be found in the final detergent formulations via the use of ethoxylated fatty alcohol sulfates as cleansing agents.

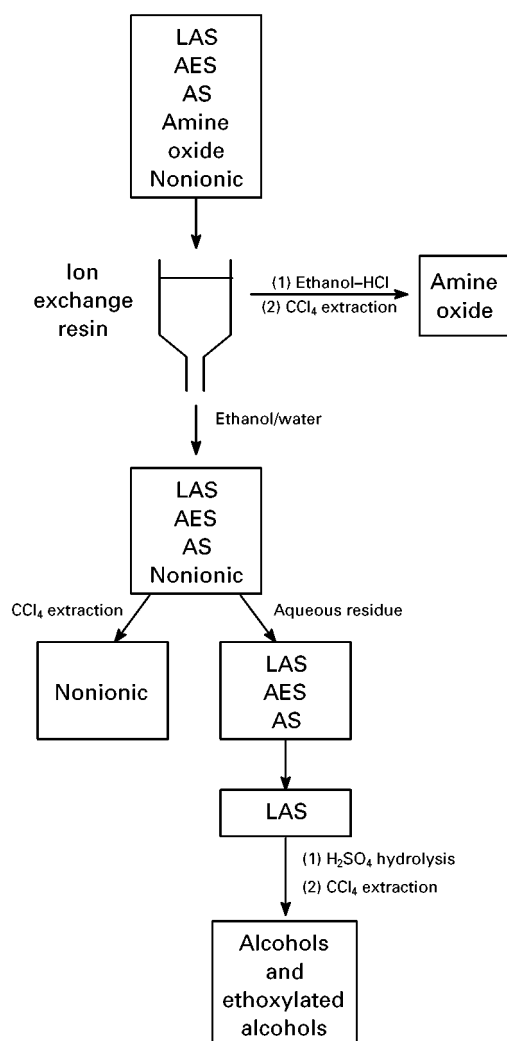

1,4-Dioxane is commonly determined by GC. A simple method applied to shampoos, requiring minimal sample preparation (dilution with water containing the internal standard isobutanol and direct injection), is carried out with packed column (15% OV-1 on 100/120 Chromosorb WHP) and FID (injection temperature 185°C; detector temperature 325°C; temperature programme 85°C (2 min), 5°C min⁻¹ to 95°C, followed by clean-up step). Linearity is in the concentration range 1–250 mg kg⁻¹; limit of detection 1 mg kg⁻¹.

An alternative technique than can be applied to different cosmetic matrices is GC-MS with selected ion monitoring (SIM); prior to analysis, rapid and efficient purification from the interfering materials of the cosmetic products is achieved by use of combined silica/octadecylsilica cartridges (limit of detection 3 mg kg⁻¹).

Scheme 1 shows a procedure useful for separation and quantitation of a hypothetical detergent product (liquid or powdered) formulated with different types of active ingredients: amine oxide, ethoxylated alcohols (nonionic), alcohol sulfate (AS), ethoxylated alcohol sulfates (AES) and linear alkyl sulfonates (LAS). Under basic and neutral conditions, amine oxide behaves as a nonionic material, while under acidic conditions it acts as a cationic agent.

A sample (~5 g) of liquid detergent or of the alcohol-soluble material (1–2 g) from a powdered detergent is dissolved in a minimum volume of ethanol–water (1:1) and passed through a strong cationic ion exchange column (Dowex 50WX4, 200–400 mesh, sulfonic acid form). Elution with ethanol–water (1:1) separates anionic and nonionic surfactants from amine oxide selectively absorbed on the resin. The amine oxide is eluted from the column with 1 mol L⁻¹ ethanolic hydrochloric acid and the eluate, after neutralization, is extracted with carbon tetrachloride. The isolated amine oxide fraction can be further characterized by NMR, IR or GC and quantified by a titration method: under acidic conditions amine oxides are determined as quaternaries with a standard alkylbenzene sulfonate and methylene blue indicator (see Cationic Surfactants). This method does not distinguish amine oxides from their precursor alkyl dimethylamines: the latter can be analysed by gas liquid chromatography (GLC).

If the amine oxide distribution and average molecular mass are unknown, they can be determined by packed column (Apiezon L on 60/80 Chromosorb W.

Scheme 1 Separation of different types of surfactants. AS = alcohol sulfates; AES = ethoxylated alcohol sulfates; LAS = linear alkyl sulfonates.

HMDS) GC: these compounds pyrolyse to 1-olefins (column temperature 280°C; injection temperature 240°C; detector temperature 330°C) and pyrolysis is essentially complete over the range of C₁₂ to C₁₈ alkyl chains. Alkyldimethylamines do not decompose in these conditions and their peaks are well separated from olefins: therefore determination of the precursors should be possible by the use of a suitable internal standard.

The aqueous alcohol phase containing free nonionic ethoxylated alcohols, sulfated anionic and sulfonated anionic material is extracted with carbon tetrachloride to separate nonionic surfactants, which can then be analysed according to one of the methods mentioned previously. The aqueous alcohol residue containing only sulfated and sulfonated anionic materials is concentrated *in vacuo* to remove the alcohol

and then hydrolysed with 1 mol L⁻¹ sulfuric acid. Hydrolysis converts all the sulfated anionic material to ethoxylated alcohols or fatty alcohols (the sulfonated anionic fraction is not affected by acid hydrolysis), which, after neutralization, can be recovered by carbon tetrachloride extraction.

The remaining ethanol-water phase containing sulfonated species is evaporated and the sulfonate is recovered and weighed by a salting out procedure; alternatively, it can be qualitatively and quantitatively analysed by the methods previously described.

Cationic Surfactants

Cationic surfactants are devoid of detergent or foaming properties, but are excellent hair conditioners: for these reasons their use in toiletries is limited to formulations of specific shampoos. Table 3 shows the main types of cationic surfactants used in cosmetics.

The ion pair extraction technique has proved suited for the determination of cationic surfactants by two-phase titrations and/or by spectrophotometry (the method is based on extraction of an ion pair between surfactant and dye, which is the basis of the well known Epton Methylene blue and The Cosmetic, Toiletry and Fragrance Association (CTFA) mixed indicator method). In the two-phase titration of cationics by lauryl sulfate in the presence of a suitable indicator dye (Methylene blue, Thymol blue, Bromophenol green, disulfine blue–dimidium bromide), the dye-surfactant ion pair is extracted almost completely by the organic solvent chloroform or methylene chloride.

When the titrant (an oppositely charged surfactant) is added, surfactant-surfactant ion pair formation takes place. The end point is indicated when enough titrant is added so that the small amount of the dye present is displaced from the dye-surfactant ion pair and returns to the aqueous phase. Alternatively, the dye-surfactant ion pair can be spectrophotometrically determined after chloroform extraction from the aqueous solution.

Using Bromophenol blue as dye indicator, it is possible to quantitate cationic surfactants and the corresponding amines when both are present in a detergent mixture. It has been shown that with long-chain quaternary ammonium compounds (cetyltrimethylammonium bromide), Bromophenol blue forms two different compounds: in alkaline solutions a blue di(cetyltrimethylammonium) salt, but in acid solution a yellow mono(cetyltrimethylammonium) salt.

Hence cationics can be estimated spectrophotometrically in two different ways, as the blue di-salt in

Table 3 Cationic surfactants

Type	General structure
Alkyltrimethylammonium halides	$\left[\begin{array}{c} \text{Me} \\ \\ \text{R}-\text{N}-\text{Me} \\ \\ \text{Me} \end{array} \right]^+ \text{X}^- \quad \text{R} = \text{C}_{12}-\text{C}_{18}$

Alkylisoquinolinium halides/saccharinates	$\left[\text{C}_8\text{H}_7\text{N}-\text{R} \right]^+ \text{X}^- \quad \text{R} = \text{C}_{10}-\text{C}_{18}$

alkaline solutions (absorbance maximum at 606 nm) and as the yellow mono-salt in acid solutions (absorbance maximum at 416 nm).

Separate estimations of the quaternaries (which do not hydrolyse) and the amine salts (which can hydrolyse easily in alkaline solutions) can be carried out working at different pH values: a higher pH will decrease the contribution of the amine even more because the higher the pH, the greater the hydrolysis of the amine salts into the amine and removal by the organic solvent. Determination of the amine salts in the presence of cationics can be carried out by estimating the total cationics in acid solution and the quaternaries only in alkaline solution: the amine content is obtained by difference. The spectrophotometric de-

termination of cationic surfactants with Orange II as dye indicator has the same kind of applications: dye salts are determined at 490 nm after chloroform extraction from aqueous solutions of surfactants and excess of Orange II dye: Orange II reacts with a 1 : 1 stoichiometry with cationic tensides and the molar absorptivity and the wavelength of maximum absorbance for the dye salts in chloroform are independent of the reacting surfactant. Isolation of dye salt in chloroform can be also used as a means of estimating average equivalent weights of commercial cationic surfactants.

By selective changing of the pH, the method might be applied for quantification of cationic precursors such as amines and amine oxides of amphoteric sur-

factants and of mixtures of amine and quaternary ammonium compounds.

The prerequisite for the extraction method is the formation of a lipophilic surfactant-dye ion pair which is then extracted into chloroform or methylene chloride. However, there are many cationic polymers used as hair conditioners that do not form lipophilic ion pairs, such as cationic polypeptides, and in addition many surfactants form an emulsion during extraction with lipophilic solvents, causing problems in determining the end point. In all these cases, quantitative analysis of cationic surfactants can be performed by a potentiometric method using a 'surfactant' electrode and sodium dodecyl sulfate as titrant.

Quaternary ammonium salts are not amenable as such to GC because of their low volatility and limited thermal stability. Long chain quaternary ammonium compounds undergo extensive but reproducible decomposition in a classical gas chromatographic system, to tertiary amines and alkyl halides. This chromatographic behaviour has led to the development of an analytical approach carried out with dedicated instruments such as a Curie point pyrolyser or a filament pyrolyser coupled to a GC-MS system, which has been applied both for structure elucidation (distribution of homologous compounds) and for quantitative determination of cationic surfactants in various matrices.

Long chain *N*-alkylpyridinium (alkyl = C₁₀-C₁₈) salts can be determined by GLC of the reduction products obtained by treatment with sodium tetrahydroborate and nickel(II) chloride. The procedure is useful for routine analysis of *N*-alkylpyridinium salts, as the reduction to perhydrogenated derivatives takes place quantitatively and cleanly in aqueous media at room temperature with easily handled reagents.

The most promising and convenient approach is LC, although its application is limited to UV-absorbing quaternaries (quantification of both UV- and non-UV-absorbing quaternaries can be achieved with a LC system coupled to a conductivity detector). Both normal-phase ion pair LC and reversed-phase LC have been used for analysis of cationics: reversed-phase chromatography is common but problematic, since these compounds mostly elute from octadecylsilica columns as badly tailing peaks.

The addition of ion-pairing agents and/or quaternary amines to the mobile phase generally does not eliminate this unwanted phenomenon. The substitution of an octadecylsilica by a polymeric polystyrene-divinylbenzene column was found to afford a considerable improvement in the peak shapes. For example, a homologous series of alkylbenzyl-

dimethylammonium and alkylpyridinium halides with C₁₀-C₁₈ alkyl groups can be separated by employing porous microspherical poly(styrene-divinylbenzene) gel as the stationary phase and 0.5 mol L⁻¹ perchloric acid in methanol as the mobile phase (the logarithm of the capacity factor for each homologous series is directly proportional to the alkyl chain length). Figure 3 shows the reversed-phase liquid chromatograms of a homologous series (C₁₂-C₁₈) of *n*-alkylbenzyltrimethylammonium chlorides obtained under different experimental conditions.

The mass spectrometric soft ionization techniques (FD, FAB) allow a rapid and unequivocal structure elucidation of the components of a mixture of cationic surfactants. FAB in the positive ion mode gives unambiguous spectra, with abundant molecular ions and no fragmentation, furnishing detailed information on the length of both the alkyl and the ethoxylate chains in polyethoxylated derivatives (these last compounds are frequently used as hair conditioners).

Amphoteric Surfactants

By definition, amphoteric surfactants are those that have anionic or cationic properties depending on the pH and that have an isoelectric point. Because of the highly nucleophilic character of oxygen, amine oxides also have salt formation potential, and for this reason their analysis is similar to that of amphoteric surfactants.

Table 4 shows the main amphoteric types produced today: alkylamido and alkyl betaines (and their respective amine oxides), alkylamido- and alkylsulfobetaines, amphoglycinates (formerly imidazolines).

Among the surfactants, amphoteric surfactants are those more prone to contamination from intermediates, since their synthesis involves several reaction steps.

Alkylamidobetaines are synthesized from the intermediate amidoamines, which in turn are obtained by reaction of fatty acids with amines (mainly dimethylaminopropylamine); the amidoamines react with sodium monochloroacetate in aqueous solution (alkaline medium) to give betaine derivatives (eqn [I]):

The corresponding amine oxides are prepared by oxidation of the intermediates amidoamines with hydrogen peroxide in aqueous solution.

In a similar way, alkylbetaines are prepared by carboxylation (with sodium chloroacetate) of the

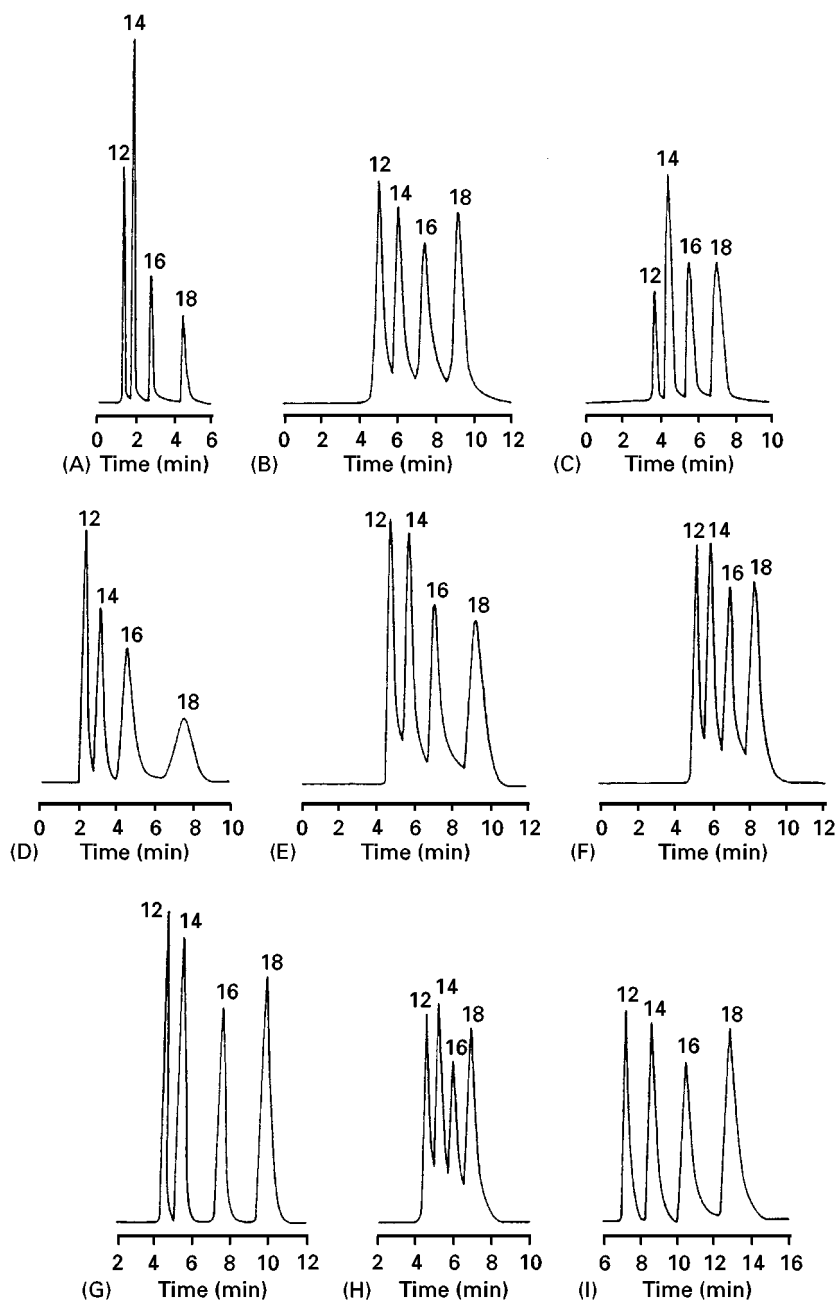

Figure 3 Reversed-phase LC peaks of a homologous series of *n*-alkylbenzyltrimethylammonium chlorides (cationic surfactants). LC conditions: all mobile phases contain 0.1 mol L^{-1} sodium perchlorate (pH 3); (A) acetonitrile–water (9 : 1); (B) acetonitrile–water (1 : 1); (C) acetonitrile–water (7 : 3); (D) methanol–water (9 : 1); (E) methanol–water (3 : 2); (F) methanol–water (17 : 3); (G) THF–water (3 : 2); (H) THF–water (1 : 1); (I) THF–water (3 : 2) (THF = tetrahydrofuran). Stationary phases: octadecylsilica (A, D, G); cyanopropylsilica (B, E, H); phenylpropylsilica (C, F, I). (From Abidi SL (1985) *Journal of Chromatography* 324: 209–230.)

alkyldimethylamines according to eqn [II]:

Sulfobetaines are synthesized according to eqn [III]:

Table 4 Amphoteric surfactants

Type	General structure	
Alkylbetaines	$R-N^+(CH_3)_2-CH_2COO^-$	$R = C_{12}-C_{18}$
Alkylamine oxides	$R-N(CH_3)_2 \rightarrow O$	
Alkylamidobetaines	$R-CO-NH-(CH_2)_n-N^+(CH_3)_2-CH_2-COO^-$	$R-CO = \text{fatty acids}$
Alkylamidoamine oxides	$R-CO-NH-(CH_2)_n-N(CH_3)_2 \rightarrow O$	
Amphoglycinates	$R-CO-NH-CH_2-CH_2-N \begin{cases} CH_2-CH_2OH \\ CH_2-COOH \end{cases}$	$R-CO = \text{fatty acids}$
Sulfobetaines	$R-CO-NH-(CH_2)_n-N^+(CH_3)_2-C_3H_6-SO_3^-$	$R-CO = \text{fatty acids}$

The position of the sulfo group is not certain, and the resulting amphoteric surfactants are thought to be a mixture of the 2- and 3-sulfopropylated quaternary ammonium compounds.

Amphoglycinates are prepared by reaction of fatty acids with aminoethylethanolamine to give intermediate cyclic compounds, imidazolines (it is common knowledge that this first step does not produce the linear amides). By carboxylation with sodium chloroacetate in aqueous solution, ring opening occurs with formation of amphoglycinates that are not of uniform composition.

Isoelectric point determination is the first measure to identify amphoteric surfactants: this can be carried out by conductivity titration, potentiometric titration or electrophoresis (isoelectric focusing). By potentiometric titration, the following isoelectric points have been determined: alkylamidobetaines ~ 7.0 ; alkylbetaines ~ 6.0 ; alkylamidoamine oxides ~ 8.5 ; alkylamine oxides ~ 9.0 .

TLC on silica gel plates with chloroform-methanol-ammonia (30:50:2) or ethanol-chloroform-ammonia (45:40:15) as mobile phases rapidly distinguishes and identifies different amphoteric, even when present in detergent formulations; detection is with 0.1% Bromophenol blue followed by treatment with 0.1% sodium periodate in aqueous solution.

IR spectroscopy is an alternative method for identification of amphoteric: in the case of amino oxides, special precautions must be taken during preparation of the samples (freeze-drying and not drying at 105°C must be used to remove the water, otherwise the N-O bond will be broken). The typical N-O bands are at approximately 960 and 930 cm^{-1} for both alkylamido and alkylamine oxides; for the alkylamido derivatives, the secondary amide bands at $c. 3300$, 1640 and 1550 cm^{-1} are diagnostic; the characteristic bands of betaines are at 1605 , 1402 , 1340 cm^{-1} (carboxylate bands), 890 cm^{-1} (quaternary N band), and 3275 , 1633 and 1549 cm^{-1} (secondary amide bands, only present in alkylamidobetaines).

The alkyl distribution in alkylamidobetaines, amidoamine oxides and amphoglycinates can be evaluated by GC, while alkylbetaines, sulfobetaines or amine oxides are preferably analysed by LC. The determination of alkyl distribution in amide derivatives is carried out after hydrolysis (with concentrated hydrochloric acid) of the amide bonds: the free fatty acids are then converted into the corresponding methyl esters by derivatization with conventional methods (such as methanol-sulfuric acid).

Reversed-phase LC (RP-18 column) is successfully used for characterization of all amphoteric, both in raw materials and in cosmetic formulations, using methanol-water (80:20) (Figure 4) or methanol-aqueous sodium hypochlorite as mobile phase. Alkylamido products (including alkylamidoamine oxides) can be detected by absorbance at 215 nm , while for alkyl distribution in alkylamine compounds a refractive index detector is recommended.

Direct analysis of amphoteric (sulfobetaines) in combination with coconut and tallow soaps can be carried out by reversed-phase LC (detection by differential refractometry) using methanol-water (85:15) as the mobile phase containing 0.2% (v/v) acetic acid ($\text{pH} \sim 4$). At this pH value, tallow and coconut soap mixtures are analysed as fatty acids and are easily separated from the sulfobetaine components.

Ionic and amphoteric surfactants can also be separated on reversed-phase columns with 2-naphthalene-sulfonic acid as counterion in the mobile phase (aqueous methanol) and detected by UV absorbance and differential refractometry. The simultaneous use of both UV and refractive index detectors allows ion pairing (ionic) and nonpairing (amphoteric) components in a mixture to be distinguished.

In the case of sulfobetaines, it is possible to separate the final product from reagents and intermediates: neither amphoteric nor long-chain fatty acids form ion pairs with the counterion in the mobile phase and they are detected by differential refractometry only. The intermediates amidoamine and long chain allyl

Figure 4 Reversed-phase LC peaks of (A) tallow-derived sulfobetaines and (B) coconut oil-derived sulfobetaines (mobile phase methanol–water, 80:20; refractive index detection). (From: Parris N *et al.* (1977) *Analytical Chemistry* 49: 2228–2231.)

quaternary ammonium chloride are detected as ion pairs by both UV absorbance and refractive index detection. Detection of ionizable surfactants as UV-absorbing ion pairs improves detection limits 100-fold over those obtained by differential refractometry.

Amphoterics are frequently contaminated with various by-products: free fatty acids; free amines (long chain amines and long chain amidoamines); and free chloroacetic acid. The determination of free fatty acids is limited to amide products, and especially to alkylamidobetaines (in this case the presence of residual amounts of free fatty acids is not a drawback, since these compounds positively affect the viscosity characteristics of the alkylamidobetaine in combination with anionics). Fatty acids can be determined as methyl esters by GC after extraction with diethyl ether of the dried product.

Unlike alkyl dimethylamines, whose presence in alkylbetaines and alkylamino oxides is undesirable, residual levels of long chain amidoamines in alkylamidobetaines are ‘cosmetically’ acceptable (they increase viscosity and have foam booster properties).

Titration methods for the determination of amine residues are primarily used for alkylbetaines or alkylamine oxides. In the method of Metcalfe, the total amine content is determined by titration (in isopropanol as solvent) with hydrochloric acid in isopropanol. After quaternarization of the residual tertiary amines with methyl iodide at 50°C, and repeated titration with acid, the total amine oxide content is determined; the tertiary amine content can be determined by subtraction (limit of detection approximately 0.5%).

LC furnishes a more selective and sensitive determination of these amine residues in all classes of amphoteric. The separation is carried out on a reversed-phase column (C_{18}) with hexane–isopropanol (60:40) as mobile phase containing 2 mmol L⁻¹ octanosulfonic acid (for the ionic pairing of the amines); detection is by UV absorbance at 215 nm for amidoamines and refractive index for alkylamines.

Alternatively, postcolumn detection can be employed for primary, secondary and tertiary amines, but not for quaternaries: the compounds separated by the LC column are first converted into the corresponding *N*-chloramines with hypochlorite; the *N*-chloramines are then treated with iodide to form triiodide, which can be monitored by its absorbance at 355 nm.

Chloroacetic acid residues can be evaluated by titration or by chromatographic methods. In the titration method, the first step involves estimation of total chlorine content by silver nitrate, after sodium hydroxide hydrolysis of the sample (2 h under reflux: under these conditions chloroacetic acid is hydrolysed to glycolic acid and chloride). The titration of an unsaponified sample gives the chloride content. The amount of ‘organic chloride’ corresponding to chloroacetic acid is obtained by subtracting the chloride content from the total chlorine. The detection limit of the method lies at 0.03% organic chloride, equivalent to 0.08% (800 mg kg⁻¹) chloroacetic acid. Using ion chromatography with a conductivity detector (amino exchange column with a hydroxide gradient elution), the limit of detection reduces to approximately 20 mg kg⁻¹.

The low volatility of alkylbetaines hampers the use of conventional EI and chemical ionization (CI) MS for structure determination. The pyrolytic behaviour of this class of compounds has been studied under EI conditions: the most important pyrolytic process

is the intermolecular isomerization to tertiary aminoesters $(\text{CH}_3)_2\text{N}-\text{CH}_2-\text{COOCH}_3$. Although pyrolysis EI spectra are useful for structure confirmation of pure compounds, they have limited or no utility for the analysis of mixtures of constituents of unknown chain length, since the spectra are dominated by the ions generated by C-N cleavage and the intensities of the molecular ions of the esters are low.

An alternative approach to structure determination is FD-MS, which gives as prominent ions the protonated species $[\text{M} + \text{H}]^+$; intermolecular alkyl transfer also occurs during field desorption, resulting in mass spectra containing structurally diagnostic adduct ions (methyl, ethyl, propyl groups linked to nitrogen readily undergo intermolecular transfer to give $[\text{M} + \text{CH}_3]^+$, $[\text{M} + \text{C}_2\text{H}_5]^+$ and $[\text{M} + \text{C}_3\text{H}_7]^+$). The presence in the mass spectra of several other

Figure 5 (A) Positive ion and (B) negative ion FAB mass spectra of cocamidopropylbetaine (amphoteric surfactants). (From Maffei Facino *et al.*, 1989.)

adduct and fragment ions (whose relative intensities strictly depend on emitter current) complicates the analysis of complex mixtures by this technique.

FAB-MS in the positive or negative ion mode is more promising, since gives not only an immediate fingerprint of the alkyl distribution in a mixture of amphoteric surfactants, but also direct information on the presence of contaminants.

As is shown with a commercial sample of cocamidopropylbetaine, in the positive ion mode (Figure 5A) the protonated (a series) and cationized (b series) molecular ions of the propylamidobetaine derivatives of coconut fatty acids (C_{12} – C_{18}) can easily be detected; the mass spectra also contain a few ions (at m/z 238, 240, 268, 296, 322, 324) that are due to fragmentation reactions (loss of a dimethylaminoacetic acid residue and loss of the carboxylic group) and some ions that, as determined by MS-MS (parent scan mode) correspond to the protonated molecular species of the dimethylaminopropylamide derivatives $[R-CO-NH-(CH_2)_3-N(CH_3)_2 + H]^+$ of fatty acids present in the mixture as unreacted materials (ions at m/z 283, 285, 313).

Negative FAB ionization cannot be used for identification of amphoteric surfactants because these compounds do not give $[M-H]^-$ ions, but it is an excellent tool for a rapid detection of unreacted fatty acids, which under these conditions give abundant deprotonated molecular ions $[M-H]^-$ (m/z 143 caprylic; m/z 171 capric; m/z 197 laurylic; m/z 199 lauric; m/z 227 myristic; m/z 255 palmitic; m/z 281 oleic; m/z 283 stearic acid) (Figure 5B). Where alkyl (C_{12} – C_{14}) betaines and cocamidopropylbetaine have been identified, this approach can also be successfully applied for the rapid detection of amphoteric surfactants in finished detergent formulations.

Recent Developments

The more recent developments in the field of surfactants analysis, in raw materials, in detergent formulations, or in environmental samples, are all based on the application of new mass spectrometric soft ionization techniques (thermospray and atmospheric pressure ionization (API)). These techniques are more rapid and versatile than conventional FAB-MS, which is dependent upon the surface activity of the sample in a given viscous liquid matrix and requires time-consuming screening of the matrix compounds to achieve maximal ionization response.

Thermospray mass spectrometry coupled to reversed-phase LC has been applied for the quantitative determination of linear primary alcohol ethoxylate (AE) surfactants in environmental samples at levels from 25 to 102 ppb (total AE), corresponding to

a range of individual AE concentration from 60 ppt to 2.17 ppb. The method is able to distinguish highly branched propylene-based alcohol ethoxylates from isomeric linear ethylene-based alcohol ethoxylates.

Positive ion atmospheric pressure chemical ionization mass spectrometry (APCI-MS) has been successfully applied to the determination of the oligomer distribution of alkylphenol polyethoxylates and fatty alcohol polyethoxylates. Positive ion and negative ion API-MS techniques have been used for quality control of the individual steps of the manufacturing process (intermediates and final products) of new classes of anionic surfactants, the alkylpolyglucoside esters of sulfosuccinic, citric and tartaric acid. With both techniques, the complex mixtures can be injected directly into the ion source without prior chromatographic separation, and the constituents are identified on the basis of quasi-molecular ions: cationized ions or solute-solute cluster ions in positive ion mode and deprotonated ions in negative ion mode.

CRUDE OIL: LIQUID CHROMATOGRAPHY

B. N. Barman, Equilon Enterprises, LLC, Houston, TX, USA

Copyright © 2000 Academic Press

Introduction

Chromatographic methods that utilize liquid mobile phases include open-column liquid chromatography, high performance liquid chromatography (HPLC), size exclusion chromatography (SEC) and thin-layer chromatography (TLC). These techniques have been widely applied for the evaluation of crude oils (as well as their subfractions) for their quality, processability or hazards. This overview covers various approaches to the characterization of crude oils by these techniques. Specific applications, operational advantages and limitations of these methods are also highlighted.

The major applications of open-column liquid chromatography and HPLC to the characterization of crude oils and related materials including residua, topped crude oils, coal liquids or shale oils involve preparative fractionation for the determination of hydrocarbon types or class separation to be followed by the determination of important subgroups and individual components. There are also numerous reports where analytical HPLC with various detection schemes has been applied to the quantitative characterization of crude oils as well as other fossil fuels.

Crude oils are usually fractionated into several compound classes according to their molecular structures. A majority of class separations have dealt with the determination of saturates, aromatics, resins (or polars) and asphaltenes (SARA). Saturates consist of paraffinic and naphthenic compounds. If olefins are present in the sample, they are usually grouped with saturates. Aromatics range from alkylbenzenes

(and other monoaromatics) to polycyclic aromatic hydrocarbons (PAHs). The polars are usually aromatic in nature and consist of compounds that may contain nitrogen, sulfur and oxygen as heteroatoms. Asphaltenes are highly condensed aromatic structures.

Conventional TLC with silica and alumina adsorbents provides separation of components from crude oils based on their polarity. TLC with flame ionization detection (TLC-FID) has been applied for the determination of hydrocarbon types. SEC has been particularly useful for the characterization of heavy crude oil fractions.

Open-Column Liquid Chromatography

Crude oils have been fractionated into saturates, aromatics, resins and asphaltenes using open-column liquid chromatography. Asphaltenes are *n*-pentane, *n*-hexane- or *n*-heptane-insolubles depending on the *n*-alkane used. The *n*-alkane-soluble materials, termed maltenes, are usually fractionated on a silica or alumina column using appropriate solvents. In general, saturates are extracted with an *n*-alkane (such as *n*-hexane) followed by elution of aromatic and polar fractions with solvents or solvent mixtures of higher eluotropic strengths. Quantitative data are obtained by the gravimetric determination of each fraction after evaporation of solvent or solvent mixture. Rotary evaporation under mild vacuum is a common practice for the concentration of the collected fractions.

A crude oil separation scheme is shown in **Figure 1**. Maltenes are obtained by precipitation of asphaltenes from the crude oil using *n*-heptane. Using column liquid chromatography on alumina, and solvents or solvent mixtures as indicated in Figure 1, fractions enriched with saturates, aromatics I and II and polars can be obtained. The aromatics I fraction contains

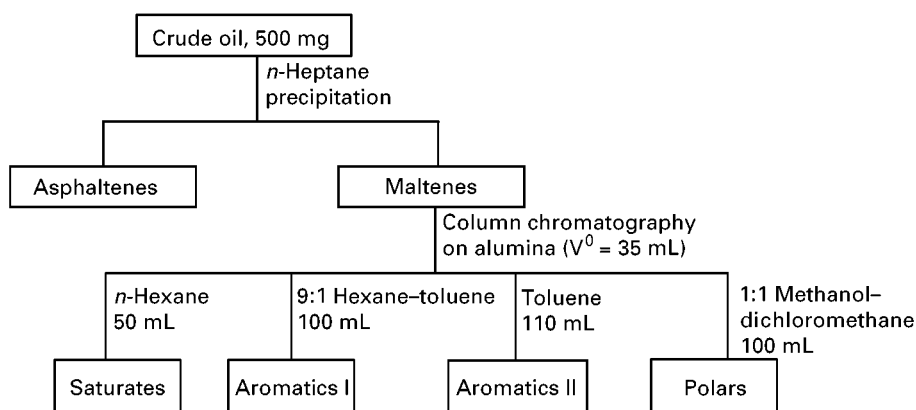

Figure 1 Fractionation of crude oil by open-column liquid chromatography. Column void volume $V^0 = 35$ mL.

monoaromatics, and aromatics II fraction is composed of diaromatics and polycyclic aromatic compounds.

Many special separation schemes have been applied to obtain fractions enriched with specific types of compounds by tailoring the adsorbents as well as the eluting solvents. Beside enrichment and type separation of hydrocarbons, the following have been typical separation schemes for the characterization of crude oil.

1. Solubility fractionation of crude oil with solvents of increasing eluotropic strength, for example, in the order of *n*-pentane, cyclohexane, toluene and methylene chloride.
2. Crude oil fractionation of sulfur and nitrogen compounds for their characterization or identification by other methods.
3. Fractionation of PAHs for their determination, ring number distribution and degree of alkylation.
4. Fractionation of saturates into *n*-alkanes and cyclic plus iso-alkanes using a 0.5 nm molecular sieve column.
5. Fractionation of acidic and basic materials from crude oil using anion exchange and cation exchange resins, respectively.

ASTM D2007 clay-gel method (approved by the American Society for Testing and Materials for the determination of characteristic groups in rubber extender and processing oils and other petroleum-derived oils) has been applied to hydrocarbon-type determination of crude oils. In this method, two glass percolation columns are connected in series with the upper column containing clay and the lower one having clay at the top and silica gel at the bottom. The sample solution in pentane is added at the top of the upper column. *n*-Pentane is then used to elute saturates from clay and silica, leaving polars on the clay

and aromatics on the silica. After removing residual aromatics from the clay adsorbent by washing with *n*-pentane, polars are desorbed with a 1:1 toluene-acetone mixture. Saturates and polars are determined gravimetrically by complete evaporation of solvents from the *n*-pentane and toluene-acetone fractions, respectively. The amount of aromatics is calculated by difference or, if desired, aromatics can be recovered by Soxhlet extraction using toluene.

Both small (mg or less) and large (multigram) scale fractionations of crude oil can be carried out by open-column solid-liquid chromatography to obtain fractions for further evaluation. These fractions are analysed by a host of analytical techniques such as gas chromatography (GC), pyrolysis GC, HPLC, infrared (IR) spectroscopy, and nuclear magnetic resonance (NMR) spectroscopy. Elemental compositions for C, H, N, S, O, V and Ni can also be determined.

Class separation by open-column liquid chromatography is labour-intensive and often suffers from inaccuracies due primarily to overloading effects that result in cross-contamination of hydrocarbon types. Moreover, there is possible loss of light components during evaporation of solvent from a collected fraction that can add significant uncertainties in the quantitative data. There can also be recovery problems arising from irreversible adsorption of some compounds on the adsorbents.

High Performance Liquid Chromatography

Modern HPLC provides both preparative and analytical scale separation of hydrocarbon types from crude oils. Preparative separation is carried out primarily for gravimetric determination of hydrocarbon types after the removal of solvents from the collected fractions. HPLC offers flexibility to allow separation

of different compound types based on their polarity and affinity using various solvents and adsorbents. An HPLC system can also be automated. Since rapid fractionation of materials for collection is possible by HPLC, the method offers a much desired alternative to lengthy and multistep open-column liquid chromatography.

Crude oils are complex materials consisting of hundreds of individual compounds of different sizes and molecular structures. The resolution level obtained during initial separation of crude oil for compound classes by HPLC is often marginal. Therefore, when determination of individual compounds or functionalities is involved, fractions from the initial HPLC separation are subjected to offline or online analysis by high resolution chromatographic or spectroscopic techniques.

Columns and Solvents

Both analytical and preparative scale separations of hydrocarbon types by HPLC have been carried out on commercially available silica, aminopropylsiloxane-bonded silica, 2,4-dinitroanilinopropylsiloxane-bonded silica or cyanopropylsiloxane-bonded silica columns. Amino- and cyanopropylsiloxane columns have been used extensively in the class separation of crude oils and other fossil fuels.

n-Hexane and *n*-heptane have been the most commonly used mobile phases for the separation of saturates from other hydrocarbon classes. Mobile-phase modifiers such as methylene chloride, chloroform, tetrahydrofuran, methanol or 2-propanol have also been used to facilitate the elution of aromatics and polars.

Preparative columns can be much larger in size (with typical column dimensions 80×0.6 cm compared to 25×0.46 cm or less for the analytical column) to allow the separation of a few tenths of a gram or more of sample in each run. The particle size of the porous packing materials can also be much larger than that for the analytical column (50–100 versus 5–10 μm). Typical flow rates for preparative separations are 20 mL min^{-1} or higher, compared to 2 mL min^{-1} or less for analytical separations. Separation times in both cases can be 30 min or less.

Detectors

The choice of detectors for the quantitative determination of various compound classes has been a major concern in HPLC. Conventional diode-array UV detector and differential refractive index (RI) detector are commonly used with HPLC. A UV detector is not suitable for saturates as they do not have chromophores. The response from a UV de-

tector at a specific wavelength varies with the number of aromatic rings, or with the isomeric compounds having the same number of aromatic rings. The very small difference in the RI of *n*-hexane (or *n*-heptane) and saturates is a serious limitation of an RI detector to be highly effective for the determination of saturates. The RI responses from aromatics and polar compounds are much lower compared to those from UV detection. The response factors of different hydrocarbon types, defined as peak area per unit concentration for both RI and UV detectors, show variations with many factors, including the crude oil, column type, column dimensions and mobile phase. Therefore, experimental response factors are often determined by preparative separation and collection of different hydrocarbon groups followed by analytical separation and detection of the collected fractions. For hydrocarbon-type analysis, each calibration is only valid for samples of the same source of crude oil.

Some special HPLC detectors, including FID, mass spectrometric detector (MSD) and evaporative light-scattering detector (ELSD) have been used in conjunction with HPLC separation of crude oils or their high boiling residua. These detectors have some attractive features. FID and ELSD are more sensitive than RI detectors and provide reasonably uniform response factors for different hydrocarbon types. MSD provides detection of materials with high sensitivity and specificity, and affords valuable information on molecular weight, structure and functionality of the molecules.

Although both FID and MSD have been successful as universal detectors in gas chromatography, the use of these detectors with HPLC has been limited, primarily because of the lack of effective interfaces to remove the mobile phase and to transport the sample to the detection system. A rotating disc FID has been demonstrated with samples boiling above 340°C to obtain hydrocarbon-type data covering a wide range of compositions. HPLC-MSD with thermospray or moving belt interface has been applied to the characterization of heavy hydrocarbons.

The ELSD has been applied to the hydrocarbon-type determination of fossil fuels boiling above 315°C (600°F). With the ELSD, mobile phase containing the analyte is nebulized with an inert gas (such as nitrogen) and sprayed into a heated drift tube where the mobile phase is vaporized, leaving behind a fine mist of dry micrometre-sized droplets in solvent vapour. As the sample particles pass through a flow cell, they scatter light from a laser beam to produce a signal. The mass versus signal from ELSD is usually non-linear. However, the signal can be linearized using a power-law model $c = ms^b$, where c and s are mass

and signal, and m and b refer to the proportionality constant and power-law exponent, respectively.

Element-specific detectors such as graphite furnace atomic absorption (GFAA) detector and inductively coupled plasma-atomic emission spectrometry (ICP-AES) detector have been interfaced with HPLC for the speciation of metal-containing compounds, including metal porphyrins. Electrochemical detectors have been applied to the detection of electroactive compounds such as phenols.

Separation Schemes

There have been a few efforts to optimize separation between hydrocarbon groups or subgroups. Most involve trials with the separation and detection of model compounds expected to be present in the sample. In almost all previous HPLC studies of crude oils and related materials, instruments have been automated for separation, detection and collection of fractions.

A simple HPLC separation scheme (scheme A) is shown in **Figure 2** where a single six-port valve and a single column (or a series of columns) have been used. Usually, deasphalted crude oil solution in hexane is injected for analysis by HPLC. The saturates and neutral aromatics (monoaromatics, diaromatics, triaromatics and tetraaromatics) are separated first with the forward flow of hexane. After this, the valve-switching causes a reversal of mobile-phase flow through the column, allowing the backflushing of the column for the elution of polar compounds. The cut point between saturates and aromatics is determined by an RI detector while cut points between aromatic ring subfractions as well as polar compounds are determined by a UV detector.

Both resolution and selectivity of hydrocarbon type separations can be enhanced using different column types and multiple mobile phases during a single run. A solvent with higher eluotropic strength than an n -alkane or a multisolvent step gradient has been found to be more effective for total recovery of aromatic and polar compounds.

A separation scheme B (reported by Pearson and Gharfeh, 1986) utilizes two pumps, two six-port valves, one cyanopropyl silica column and two aminopropyl and cyanopropyl silica columns. Using n -hexane from the first pump, the sample is allowed to pass through the cyanopropyl silica column where polar compounds are strongly retained. The saturates and aromatics pass on to the two aminopropyl and cyanopropyl silica columns. The cyanopropyl silica column is then isolated using the first switching valve. As soon as the saturates elute, the second valve is used to backflush the aminopropyl and cyanopropyl silica columns for the elution of aromatics. The polar compounds are then eluted by back flushing the cyanopropyl silica column with methyl *tert*-butyl ether from the second pump. **Figure 3** shows a chromatogram of a crude oil residue obtained by the separation scheme B using FID for detection. Since a crude oil residue meets the boiling point requirements for an ELSD to be quantitative, ELSD can also be applied to detect and determine its components separated by HPLC.

Special HPLC Applications

Both preparative HPLC and analytical HPLC have been utilized for sample clean-up and separation of specific groups of compounds for online or offline characterization by capillary GC, GC-mass spectrometry (MS) or GC-element-specific detection. Column-liquid chromatography or semipreparative

Figure 2 A scheme for hydrocarbon-type separation from crude oil by HPLC.

Figure 3 HPLC chromatogram of a crude oil residue. (Modified with permission from Pearson and Gharfeh, 1986. Copyright 1986 American Chemical Society.)

HPLC fractionation followed by analytical HPLC have also been very effective for the determination of certain compound types, including PAHs, petroporphyrins, sulfur heterocycles, phenols and nitrogen bases such as azarenes.

Size Exclusion Chromatography

SEC is usually applied to the analysis of high molecular weight materials. Unless there are specific interactions between the column packing and the sample components, the elution of molecules in SEC is bounded by limits representing total exclusion and total permeation through macroporous particles packed into a column. In this method, the high molecular weight materials elute first, followed by smaller molecules, which is the basis for the determination of molecular weight distribution by SEC.

Typical crude oils contain compounds having low (<100 Da) to high molecular weights (>2000 Da). The average molecular weight can be around 1000–1500 Da. Since 30% or more of the materials in the crude oil may have molecular weights similar to that of the mobile phase and therefore, falling close to the total permeation limit of typical SEC columns, SEC is more suitable for the determination of molecular weights of heavy petroleum fractions derived from crude oil. Atmospheric or vacuum residua and polars and asphaltene fractions from crude oil have been analysed by SEC to monitor changes during their processing or to fractionate them into narrower cuts for further analysis. SEC can also be used as a sample clean-up technique to remove small molecules from high molecular weight materials or vice versa.

The analysis of crude oil or its fractions by SEC is carried out using a series of small pore size (usually ≤ 100 nm) poly(styrene-divinylbenzene) columns and mobile phases of tetrahydrofuran, toluene, chloroform, *N*-methyl-2-pyrrolidone or pyridine. The sample size can be 5 mg or less. Almost all detectors used with HPLC can be coupled with SEC. The most

common detectors are RI, ELSD and UV. Typical separation times are 40 min or less.

Usually molecular weight distributions of fossil samples are determined relative to narrow polystyrene standards. Although both RI and ELSD provide mass versus molecular weight distribution of the sample, a UV detector can be used for similar distribution for specific compound type, using a compound-specific wavelength. For example, distribution of petroporphyrins in polar fractions can be obtained by monitoring sample elution with a UV detector at around 400 nm. Petroporphyrin distributions have also been obtained by SEC-GFAA and SEC-ICP-AES detections.

Thin-Layer Chromatography

TLC using silica or alumina plates and appropriate solvents can provide quick class separation of a crude oil primarily for collection of its fractions. The detection methods for the separated components include visual examination of coloured spots, observation by irradiation with UV light, UV-fluorescence scanning and spraying of chromogenic or fluorogenic reagents.

Rapid and direct determination of hydrocarbon types of a crude oil can be achieved by TLC coupled with FID. In TLC-FID (which is also known as Iatroscan), thin reusable quartz rods (Chromarods) sintered with micrometre-sized silica or alumina particles are used as the stationary phase. After spotting a few micrograms of the sample, the Chromarods are developed sequentially with several solvents or their mixtures of decreasing eluotropic strengths to achieve desired separation. For example, the Chromarods can be developed first with toluene for 5 min to separate saturates plus aromatics from polar compounds. After this, they can again be developed with an *n*-alkane (such as *n*-heptane) for 30 min, for the separation of saturates from aromatics. During the second step, the position of polar compounds remains unchanged, and aromatics are distributed broadly according to their polarity or the number of aromatic rings. As an option, polar compounds can also be subdivided into two resin types by developing the Chromarods with a 9:1 chloroform-methanol mixture for 3.5 min. The Chromarods are dried in an oven after each development. Finally, each Chromarod is scanned by passing it through an oxygen-hydrogen flame for the detection of separated components.

Due to limitations in the design of the commercially available instruments, the TLC-FID method is only quantitative for samples boiling above 300°C. The low boiling materials present in the whole crude oil evaporate during development and drying. Such

evaporation may also occur when Chromarods are exposed to the flame during scanning of the adjacent rod. Therefore, TLC-FID is more suitable for high boiling residua or fractions derived from crude oils than for whole crude oils.

The three TLC-FID chromatograms in **Figure 4** have been obtained by developing Chromarods with toluene for 5 min followed by *n*-heptane for 30 min. Figure 4A demonstrates the capability of TLC-FID for the resolution of saturates and aromatics, and of the ring-based separation of aromatic compounds. Peaks 1–5 in this chromatogram are for Nujol, *n*-heptadecylbenzene, 2,3-dimethylnaphthalene, 9-methylanthracene and 9,10-dimethyl-1,2-benzanthracene, respectively. The unidentified peaks (right-hand side of Figure 4A) are for polar impurities.

A cursory examination of chromatograms of a topped crude oil in Figure 4B and of a vacuum residue in Figure 4C suggests a marked compositional difference between these two samples. Note that the vacuum residue was derived from the topped crude oil as vacuum tower bottoms after vacuum distillation. The vacuum residue contains much more polar and large ring aromatic compounds than the topped crude oil. Specifically, the amounts of saturates, aromatics and polars are 28.6, 56.8 and 14.6% (w/w) in the topped crude oil compared to 9.0, 58.5 and 32.5% (w/w), respectively, in the vacuum residue.

Unlike model aromatic compounds in Figure 4A, aromatics in both topped crude oils and vacuum residua do not show distinct peaks for different ring types. This is primarily due to chromatographic over-

Figure 4 TLC-FID chromatograms. (A) Separation of hydrocarbons by class and number of aromatic rings using a model mixture described in the text; (B) topped crude oil; (C) vacuum residue.

lap arising from degree of substitution as well as substituents of diverse chemical structures attached to the monoaromatic as well as polycyclic aromatic compounds.

Future Possibilities

At present, relevant analytical data on crude oil composition are very useful in crude oil processing as petroleum refiners are increasingly using blended feeds instead of limiting the plant operation to a single type of crude oil. The compositional data will be more important as the depletion of light and sweet crude oils continues and refineries process more heavy and sour crude oils. For process control, product quality, catalyst performance and environmental compliance, faster and better analytical approaches to crude oil characterization will become a vital part of the refinery operation. As far as liquid chromatographic methods are concerned, multistep column-liquid chromatography will be less attractive due to limitations such as lengthy turnaround times, high level of uncertainties in the compositional data, excessive solvent consumption and costs involved in their disposal. Modern HPLC, SEC and TLC-FID methods will continue to provide valuable information on crude oils. Most likely, faster and better results will be achieved through major developments in system automation for coupling these techniques with other chromatographic and spectroscopic methods. Such hyphenated techniques are already being pursued to find better approaches to the characterization of fossil fuels, including crude oils.

DECANTER CENTRIFUGES IN PHARMACEUTICAL APPLICATIONS

J. V. McKenna, Alfa Laval, Warminster, PA, USA

Copyright © 2000 Academic Press

Centrifugation continues to perform a vital role in pharmaceutical process operations. In the 1990s new enhancements to the technology attracted many new

areas of application. Growing demands for higher yields and dryer cell cake, punctuated by the pursuit of lower cost solutions, continue to keep high performance centrifuges at centre stage in the quest for better separation procedures. In addition, tighter regulations and inspection procedures continue to act as catalysts for the development of fail-safe

Figure 1 Basic decanter.

equipment for sterility and containment to meet more stringent user demands. Within this environment, a decanter (**Figure 1**), which is the most compact type of separation equipment available, is often the centrifuge of choice for producing pharmaceuticals such as erythromycin, insulin (human and animal) and many other large bulk products. These workhorse machines perform a wide range of separation duties, including liquid–solid, liquid–liquid, and liquid–liquid–solid separations and liquid–liquid extractions. Decaners have become most useful for many pharmaceutical operations including recovery and solids purity. These reliable and versatile machines are active in many of industry's typical process steps, e.g. cell harvesting, concentration and washing, cell debris removal, inclusion body recovery and purification, solvent extraction, dewatering and recovery.

Currently, the trend in solid–liquid separation is towards higher solids fractions in the fermentation process. This translates into greater productivity and lower capital costs per pound of product produced. Typical fermentation processes involve amino acids, antibiotics, bacteria, enzymes, ethanol, fungi, inorganic salts, organic acids, polypeptides, polysaccharides, steroids, vaccines, vitamins and yeasts. Decanter centrifuges are also used in extraction and fractionation processes for hormones, alkaloids, blood separation (animal) and natural product isolation.

General Operation

Normally decaners handle two- or three-phase separation of high-solids slurries (**Figure 2**). The slurry enters the centre of the bowl, and denser solid particles are sedimented against a rotating bowl wall. The less dense liquid forms a concentric inner layer. Centrifugal force compacts the solids as they are 'ploughed' out of the pond and up the conical 'beach' by a helical screw conveyor. Solids exit through dis-

Figure 2 (See Colour Plate 72). General decanter operation.

charge ports, while clarified liquid or centrate overflows the plate dams situated at the opposite end of the bowl. While decaners can handle a wide range of particle sizes, dryer cake is always produced when particle size is maximized – preferably to 2–10 μm depending upon G-force. It is important to note that in biotech lysed *Escherichia coli* separations, cakes that are 30–40% dry have been achieved with particle sizes of 1 μm or less.

In practise, decanting centrifuges provide excellent performance levels when handling slurries with significant amounts of solids (generally > 10% by volume), and are often the only choice for solids concentrations above 40% by volume. With appropriate conveyor modifications they can also be used to separate two liquids from each other or from a solid phase. The scroll of the decanter provides a continuous discharge of solids. By interposing nozzles near the beach section it is possible to provide a washing step before the solids are discharged. This method can be used to wash various crystals. In contrast to basket or disc-stack centrifuges, where liquid flow is laminar and flow patterns are relatively simple and contained, the flow patterns and consequent design calculations are more complex for decaners. Separation performance is more subject to analysis by experience and pilot testing.

Vertical Units

Most decanter centrifuges are horizontal, but vertical orientations (**Figure 3**) are also available. The same centrifugal operating principles apply to both types, and process performance is not affected by whether the axis of rotation is vertical or horizontal. The main difference between the two types lies in the seal design. A vertical machine has only one high speed rotating seal plus one low speed (42–52 rpm) or static seal, while a horizontal unit has at least three high speed seals. For this reason, a vertical configuration is

Figure 3 (See Colour Plate 73). Vertical decanter.

easier to seal. With only one sealing surface this unit is often the preferred choice when handling hazardous materials or toxic materials. Vertical centrifuges are often used in high temperature, high pressure applications for handling pressures from vacuum up to 10 bar with process temperatures from -10 to 700°F .

If floor space is a concern, vertical decanters offer distinct advantages over horizontal machines as they require 60–80% less floor area. They also provide more production per square foot with less investment in piping, foundations and real estate.

Factors of Acceptance

For small batch fermentations (100 L or less) membrane technology and mechanical filtration remain the prevalent technologies for processing diverse stream arrays. However, for large volume runs requiring environmental measures and control, decanters are normally specified for several reasons. First, the enclosed seal design of this type of centrifuge type offers inherent advantages. Decanters can be sealed hermetically for the protection of operating personnel, and offer clean-in-place operation and sterilization. Second, the efficient operation of a decanter can produce a dry continually discharged solids phase without contamination of either the product stream or the centrate. Also advancing work on new metallic finishes continues to offer promise for new sterility solutions and safeguards.

Additional factors also work in favour of these machines. Possibly foremost is the growing need to produce dryer cake. As expected, when there is less water solids require less energy for drying. Depending upon the application, decanters can produce dry solids as high as 30–95% for dry solids. The high G-force capabilities of the units can separate out even the finest particles, resulting in cleaner centrate.

The ability to operate at higher G-forces remains a goal. Indeed, high G-force separation continues to expand. Five years ago decanter centrifuges could only generate forces up to 5000 G. During that period

disc-stack centrifuges were primarily used for applications, from pilot to full production. Today decanters are capable of 10 000 G operation, making the machines competitive with disc-stack centrifuges for specific pharmaceutical applications.

Continuous operation is another reason why the industry often opts for decanters. The feed and discharge operations (solids and liquids) never cease. There is less downtime and maintenance is substantially lower than with other separation alternatives. At the same time decanters are less affected by feed variations, such as varying particle size, than filter systems which require changing media mesh sizes. The centrifuges also more efficiently separate adhesive, slimy, high viscosity or fluffy materials, which often blind or impair filters. They also provide dryer cake results for these materials than do filters.

Minimal liquid loss is also associated with decanters. Permeable filters lose liquid through absorption as well as losing fluids via filter disposals. This loss becomes critical if a high value is attached to the liquid phase. Also, filters usually separate only two phases simultaneously, requiring another pass for a third separation, while centrifuges are capable of one-step, three-phase liquid–liquid–solid separations (e.g. oil, water, solids).

Improvements to Decanters

Several changes to decanter technology have affected the performance of the machines in the last 10 years.

Settling Vanes

New conveyors have been fitted with unique incline vanes to enhance the collection area of the disc unit. Settling vanes (**Figure 4**) reduce turbulence and stratify feed flow in the clarification zone to promote settling and prevent re-entrainment of solids. This

Figure 4 Conveyor with settling vanes.

Figure 5 (See Colour Plate 74). Performance-enhancing features of a decanter centrifuge.

results in more efficient solids recovery and a 50% improvement in centrate clarity.

Hydraulic Disc (Baffle Disc)

This feature shown in Figure 5 enhances the separation of soft, gelatinous materials such as proteins, enzymes, and fermented products. The disc is used to increase the separation efficiency on hard-to-scroll materials (materials that tend to slip on the conical section of a decanter). Acting like a dam, solids build up around the disc, holding in the liquid centrate to provide ultra-deep pond settlings above the level of the solids discharge. The resulting hydrodynamic pressure compacts solids, assists scrolling, and extrudes the compacted solids past the disc and out of the centrifuge.

Dryer Cake: Plough Tile/Conveyor Innovations

New designs now provide purer and dryer cake. Recent innovations permit the centrifugal retention of solids for longer periods of time under maximum G-force. A new conveyor handling compressible solids, such as fibrous materials, has been able to produce up to 35% dryer solids in vitamin, gluten, and cornstarch processing applications.

A newly developed plough tile conveyor (Figure 6) uses scoop-shaped tiles to reduce the torque produced by the solids moving through the centrifuge. By lifting and turning the solids from the bowl wall these tiles reduce the torque, produce dryer cake, and increase capacity. The addition of this innovation enables the conveyor to achieve up to twice the throughput of standard conveyors.

Another additional improvement is the 'Kiwi conveyor' (Figure 7), a patented flightless conveyor that achieves dryer cake to improve clarity. This unique

innovation acts as a catalyst to force newer solids to move old solids out of the bowl.

Efficient Feed Zone

Redesign of the feed zone as shown in Figure 5 has helped to reduce the shear forces on the feed material as much as possible. Shear forces on the liquid stream can cause problems, especially when liquid goes from rest to bowl speed. Upgrade designs now allow for gentle acceleration and entrance into the bowl by means of a low-shear feed zone. This improvement has eliminated the need for acceleration blades.

Variable Speed and Differential Control

Programmable Logic Controller (PDC) and digital controllers are now used to control the large speed swings of a decanter's backdrive motor that are associated with differential control. These systems provide the necessary control features to monitor and stabilize a decanter's eddy current brakes, direct current motor, and alternating current variable

Figure 6 Plough tile conveyor.

Figure 7 'Kiwi' conveyor.

frequency drives to within 0.1 rpm of the desired set points. By maintaining lower differential controls, users achieve dry cake.

Centripetal Pumps and Containment

Optional centripetal pumps can be added to minimize foaming and aerosols, and gently discharge delicate pharmaceuticals without the risk of oxidation or contamination to the product stream. Such pumps help control liquid creasing and the separation efficiency of the unit.

Vapour Sealant

For applications requiring biohazard-safe, vapour-sealed operation, casing seals are available to contain pressure up to 14.4 kPa inches of water. Lip seals, labyrinth seals, and gas-purged mechanical seals are typically used. If required, decanters can be equipped with steam sterilization for aseptic steam processing.

Clean-In-Place Operation

Self-cleaning units are also available for faster and safer pharmaceutical processing. Built-in motor controls safely reduce rotation to 1 G and automatically clean the decanter's bowl and casing. This eliminates the need to tear down or dismantle the centrifuge.

Conditioning Monitoring

Together with the decanter improvements, the capability to maintain product integrity has been further enhanced by conditioning monitoring programs

available from some manufacturers. New software eliminates second guessing and enables users to analyse machines on a continuous basis, e.g. monthly, weekly, etc., by checking for new vibrational patterns due to changes in unit load, balance, or the hydraulic dynamics of the bearing. Conditioning monitoring provides real-time information about the working operation of the centrifuge. Accompanying instrumentation and probes also analyse critical areas such as bearing patterns to note changes, predict failure and prevent unexpected costly shutdowns. Data acquired and stored in the program can also be used to determine what spare parts to keep in stock.

Conclusion

The development of pharmaceutical products requires separation equipment that delivers high recoveries and high solids purity. During the 1990s decanter centrifuges closed the gap on or, depending upon the application, even surpassed the advantages once held by alternative separation devices. In centrifugation, operating costs are notably lower than with filtration devices with capital investment of hardware as the only significant cost. Decanters also require less auxiliary equipment such as secondary pumps, tanks, and extra ventilation machines. Thus large-scale pharmaceutical operations rely on continuous centrifuges to produce maximum possible amounts of dry cake and decanters are well suited to this task.

DE-INKING OF WASTE PAPER: FLOTATION

C. Jiang and J. Ma, Enzymatic Deinking Technologies,
Norcross, GA, USA

Copyright © 2000 Academic Press

Introduction

The earliest work on utilization of froth flotation for de-inking of wastepapers dates back to the 1930s. The first flotation de-inking patent was filed by Hines in 1933. However, it was not until 1952 that the first commercial flotation de-inking system was installed at a paper mill in the USA, and the first European installation was at a tissue mill in Greece in 1959. Up to 1970, the growth of flotation de-inking technology was relatively slow. However, in the past 20 years, the market has grown extremely rapidly. The world-wide flotation capacity for de-inking of wastepapers has increased from 0.2 million tons in 1965 to about 25 million tons in 1995.

De-inking is a separation process to remove inks and other nonfibrous contaminants from wastepapers. Different types of units are required to separate inks from fibres, and this mainly includes washing, flotation, cleaning and screening. The selection and operation of these units are based on the types of wastepapers and the requirements of the finished de-inked pulp. Wastepaper is commonly grouped into five categories, which include mixed paper, old newspapers, old corrugated containers, pulp substitutes and high grade de-inked. **Table 1** shows a typical wastepaper classification and the finished products obtained from different kinds of wastepapers.

De-inking is a two-stage process which involves dislodging the ink and nonfibrous contaminants from

the fibre surface and removing them by washing, flotation, cleaning and screening. Common contaminants include ink, staples, paper clips, sand, plastics and stickies. The most important and widely used de-inking process to date is the froth flotation process. This process removes the widest range of ink particles from wastepapers. Flotation alone or in combination with other processes can remove almost all types of ink particles and other contaminants from the slurry of wastepaper.

Flotation Process and Equipment

Flotation Process

Pulping The first step in de-inking wastepaper is pulping. Because of the nature of the chemicals and equipment used to pulp wastepaper, the pulping process is analogous to sulfite 'cooking'. Chemicals, together with heat and mechanical energy, are used to detach the ink particles and other contaminants from the fibres in a pulper. Pulping can be either a batch or continuous process. Newsprint mills typically use continuous pulping at a consistency of 4–8%. Other mills usually use batch pulping at a higher consistency of 8–18%.

Flotation Flotation de-inking is a selective separation process that utilizes the difference of surface physicochemical properties between the ink and fibre. Flotation chemicals are fed to the wastepaper slurry to render the ink particles selectively more hydrophobic and hence to increase the floatability. When the air bubbles are sparged into the flotation cell containing the wastepaper slurry, the ink particles get at-

Table 1 Typical wastepapers and their classification

<i>Category</i>	<i>Compositions and abbreviations</i>	<i>Finished products</i>
Old newspapers	Old newspapers (ONP), white blank newspapers	Newsprint, boxboard, tissue, paper towels
Old corrugated containers	Old corrugated containers (OCC), double linerboard kraft corrugated clippings (DLK)	Linerboard, boxboard, corrugating medium, kraft towels
Mixed paper	Mixed office waste (MOW), old magazines (OMG), sorted ledgers, computer printout (CPO), manifold white ledger (MWL), sorted office waste (SOW)	Printing and writing paper, paperboard, tissue, paper towels, magazine newsprint
Pulp substitutes	Unprinted paper and board, boxboard cuttings, printer trims, envelope cuttings	Fine paper, tissue, envelopes
High grade de-inked		Fine paper, tissue, printing and writing papers

tached to the air bubbles due to their relatively high hydrophobicity and are floated to the surface of suspension, and the hydrophilic fibres remain in the water phase.

Flotation De-Inking System

Flotation is traditionally the standard European de-inking system for old newspapers. The stocks or wastepaper slurry after pulping generally go through a soaking stage in a dump chest to swell the fibres and to improve ink detachment from the fibre.

The stock is subsequently aerated at 0.7–1.5% consistency in a series of flotation cells. Typically, six to 10 flotation cells in series (primary flotation) are required for efficient ink removal. The froth from primary flotation is subsequently cleaned in a secondary or recovery stage (usually two cells) to further recover food fibres and to decrease fibre loss. A typical and representative example of a flotation system is illustrated in Figure 1.

Most technical advances made during the past 10 years involved utilization of a combination of flotation and washing stages to remove inks from the more complex wastepaper. The concept of the post-flotation system is to add a disperger or kneader between two standard flotation stages. The dispersion or kneading stage further helps the detachment and size reduction of ink and other nonfibrous particles, and hence improves the overall flotation performance.

Evolution of Flotation Cells

Froth flotation is the most widely used separation process in modern paper mills. During the last 10 years, the development of flotation de-inking cells has been pursued more aggressively than the technologies of any other segment of the pulp and paper industry.

Initially, Denver flotation cells used in the mineral industry were installed in paper mills. These cells are open, rectangular vats, with mechanical removal of flotation froth by a rotating paddle and mechanical mixing of air and pulp suspension at the bottom. However, these cells are not currently in use.

Although the development of flotation cells for de-inking was less dramatic in the early years, there have been many changes in cell design in the last two decades. Table 2 lists the historical development of flotation de-inking cells.

The major driving forces of the evolution of modern flotation cells are the reduction in energy and water consumption, lower footprint space and an increase in efficiency and capacity. Although many changes in flotation cell design have been made, the improvements in flotation de-inking performance are not always obvious. More recently, because of the great advances in printing, coating and modification of paper by converters to impart special properties, flotation de-inking has evolved from removing ink particles only to removing an ever-increasing variety

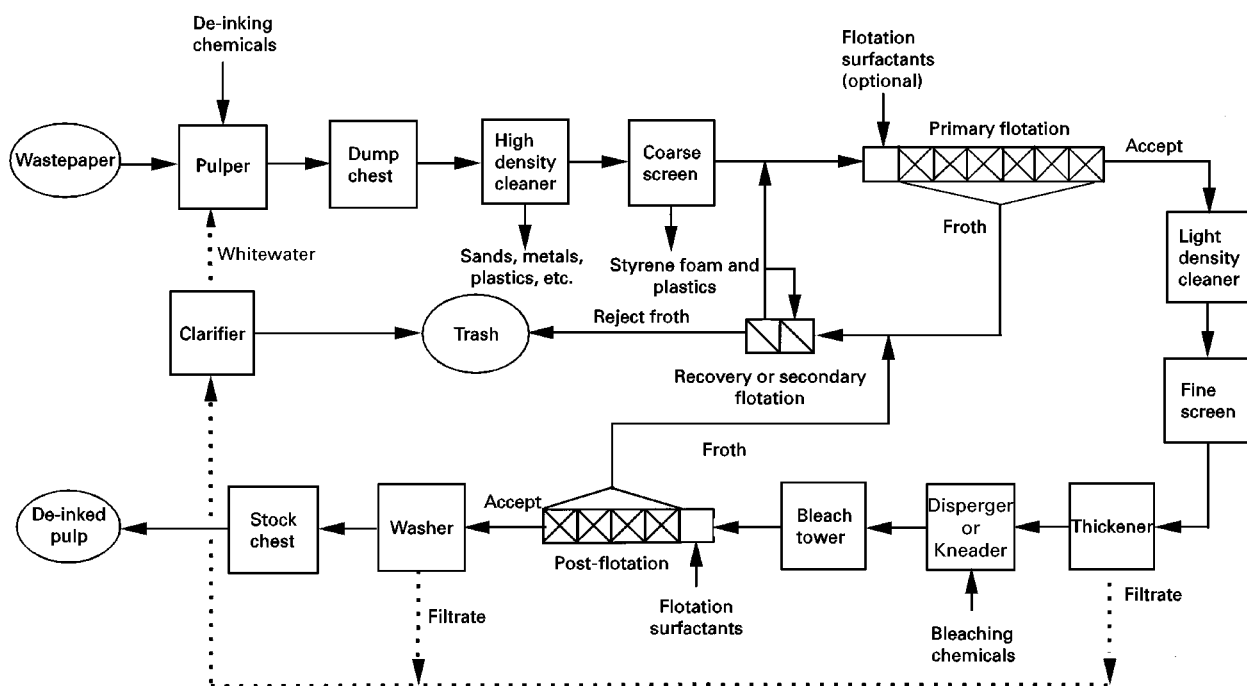

Figure 1 Flow diagram of a typical flotation de-inking mill for mixed paper.

Table 2 Historical evolution of flotation de-inking cells

<i>Year</i>	<i>Flotation cell name</i>	<i>Comments</i>	<i>Year</i>	<i>Flotation cell name</i>	<i>Comments</i>

1984	Esher Wyss CF	Step diffuser improves mixing	1996	Kvaerner Hymac column flotation cell	First cell to use two types of air spargers to provide different size air bubbles

of objectionable, noncellulosic materials. However, in terms of ink removal efficiency, older flotation cells perform satisfactorily.

Factors Affecting Pulping and Flotation

The performance of flotation de-inking is affected by many factors such as pH, consistency, temperature, ink/fibre particle size, chemical types, water hardness and air bubble size. Properly controlling these factors ensures the efficient removal of ink.

pH pH significantly affects both the pulping and flotation processes by altering the physical and chemical properties of fibres and inks. High pH helps swelling of fibres and promotes the detachment of inks from fibre. However, if the pH is too high (e.g. > 10), it may cause yellowing or darkening of lignin-containing pulps. The conventional fatty acids

and soaps used as ink collectors are only effective at alkaline pHs. Neutral pH flotation de-inking requires the use of more effective and selective nonionic surfactants.

Temperature Pulping and flotation temperatures are typically maintained at 40–55°C and 35–45°C, respectively. In general, elevated temperatures are used to improve the defibrization of special waste-paper such as wet strength paper. Lower temperature is beneficial to high stickies-containing wastepaper, such as magazines.

Consistency Consistency or dry fibre per cent weight in water has a direct impact on the ink particle size distribution. Depending on the types of waste-paper, different pulping consistencies are used. In newsprint mills, low-consistency (4–8%) pulping is generally used. However, in office paper de-inking

mills, medium (8–12%) or high consistency (12–18%) pulping is widely applied. In general, the higher the pulping consistency and the longer the pulping time, the smaller the ink particles liberated. Typical fibre consistency in flotation operation is 0.7–1.2%.

Particle size Flotation is most effective for removing ink particles ranging from 10 to 150 μm . In general, particles smaller than 10 μm and larger than 150 μm cannot be efficiently removed by flotation process.

Water hardness In newsprint flotation, fatty acids or soaps are used as ink collectors, and a moderate amount of calcium ions (100–300 p.p.m.) is required to make the ink floatable. No additional hardness or calcium ions are added when nonionic surfactants are used.

Ash or filler content There is a strong relationship between the amount of clay or fillers in the wastepaper and the ink removed in a flotation stage. Flotation de-inking becomes much more effective when the wastepaper has significant ash content. An 8–10% ash is considered a minimum requirement, and 12–14% is preferable.

Evaluation of Flotation Performance

Three major parameters are widely used in the paper industry to characterize the flotation deinking efficiency: brightness, ink removal and reject rate.

Brightness is the percentage of reflectance measurement of pulp or paper products at a wavelength of 457 nm. It is originally developed to evaluate bleaching efficiency. In general, pulp brightness increases as ink is removed. The brightness increase is usually in the order of 10–15 units for newsprint de-inking and of 5–10 units for white grades.

Reject rate is defined as the mass rate of reject to total stock fed into flotation. A main objective of flotation de-inking is to obtain the maximum ink removal at a minimum reject rate. For mixed office wastepaper (MOW), reject rate is commonly 10% and for ONP/OMG, it is about 15%.

Ink removal is calculated based on the ink concentration of the pulp before and after flotation. Image analysis techniques are used to measure ink particle size ($> 3 \mu\text{m}$), total counts and the total surface area. Effective residual ink concentration (ERIC) measurement was developed to determine the visual effect of residual inks on the de-inked pulp. The visual effect is primarily dependent on the presence of small size ink particles ($< 3 \mu\text{m}$) rather than the total ink content of the paper.

To evaluate the de-inking efficiency, both the ink removal of different size particles and brightness should be reported together with reject rate. For newsprint mills, brightness and ERIC measurements are usually employed and, for white grades, ink count measurement is very common.

De-inking Chemicals and Recipes

The use of chemicals is involved in almost every aspect of the key processes in de-inking. Chemistry is of great importance in flotation de-inking in terms of fibre swelling, ink detachment, dispersion, anti-redeposition, ink agglomeration, ink collection and removal. Most of the chemicals used for de-inking are fairly standard commodity products, such as sodium hydroxide and sodium silicate. On the other hand, some other chemicals are relatively complex and have multiple functions. In general, most de-inking chemicals are added in the pulper. Commonly used de-inking chemicals in pulping and flotation, their functions and addition points are listed in Table 3.

Pulper Chemicals

The chemicals used in the pulper depend strongly on the types of wastepaper processed. The principal chemicals used for pulping and flotation are sodium hydroxide, sodium silicate, chelating agents, hydrogen peroxide, surfactants and solvents. The roles of these major de-inking chemicals are briefly discussed below.

Sodium hydroxide Sodium hydroxide is used to promote fibre swelling and to saponify or hydrolyse the ink resins by increasing pH and alkalinity. The type and amount of alkali required in the pulper depend on the type of mechanical treatment, temperature and pulping time. However, the addition of excessive caustic soda to ground wood-containing furnishes will cause the pulp to yellow or darken. This is termed as 'alkali darkening or yellowing'. Sodium carbonate is rarely used in modern de-inking mills.

Sodium silicate Sodium silicate or water glass is frequently used in conjunction with sodium hydroxide, especially in the de-inking of groundwood papers. It not only serves as an alkali to swell fibre and as a dispersant of ink particles, but also buffers the pulp to a pH range which is favourable to the action of hydrogen peroxide.

Hydrogen peroxide Hydrogen peroxide is one of the most commonly used pulping chemicals in the

Table 3 Chemicals used in flotation de-inking and their functions

<i>Chemical</i>	<i>Structure/formula</i>	<i>Function</i>	<i>Furnish type</i>	<i>Dosage (% of fibre)</i>	<i>Addition point</i>
Sodium hydroxide	NaOH	Fibre swelling – ink break-up Saponification	All grades	0–5	Pulper

recycling of groundwood wastepaper. It is also widely used as a bleaching chemical. The addition of hydrogen peroxide in the pulper is to offset the formation of chromophores created by high alkaline pH.

Sodium hydrosulfite Hydrosulfite is mainly used as a reductive bleaching agent to bleach recycled pulp and to decolourize the coloured fibres.

Chelating/sequestering agent Chelating compounds are commonly added in the pulper to form complexes with multivalent metal ions to prevent peroxide decomposition. Diethylenetriaminepentaacetic acid (DTPA) and ethylenediaminetetraacetic acid (EDTA) are the most common chelates used in the

paper recycling industry. Compounds like DTPA and EDTA have been banned in some countries, for example, Sweden and Norway.

Dispersants Sodium tripolyphosphate and tetrasodium pyrophosphate are sometimes added to the pulper to provide multiple functions such as ink dispersion and metal chelating. Use of laundering anti-redeposition agents such as carboxymethylcellulose and sodium polyacrylate can also help disperse the ink particles, prevent redeposition of ink on the fibre, and increase de-inked pulp brightness.

Solvents Organic solvents were once widely used to dissolve waxes and varnishes, but environmental

concern has curtailed the use of these chemicals. Solvents used in wastepaper deinking include C_{12} – C_{14} hydrocarbons and glycol ethers.

Flotation Chemicals

Surfactants are probably the most important chemicals in flotation de-inking. They consist of two principal components – a hydrophilic component and a hydrophobic component. It is assumed that the hydrophilic end of the molecule attaches to the ink particle, leaving the treated surface state hydrophobic. Most surfactants used in flotation de-inking play two important roles. Firstly, they function as ink collectors that selectively render the ink particle surface more hydrophobic and facilitate ink particle–air bubble attachment. Secondly, they serve as flotation frothers that generate moderate foaming. Surfactants used in flotation de-inking can be cationic, anionic, nonionic or amphoteric, and are added either at the pulper or just before the flotation cells.

The most frequently used surfactants are fatty acids and their soaps, as well as nonionic surfactants. Cationic surfactants are not currently used in flotation cells. Commonly used flotation de-inking surfactants and their formulas are shown in **Table 4**.

Fatty acids and soaps Fatty acids and their soaps are early flotation de-inking surfactants, and are commonly used in Europe than in North America. Mixtures of fatty acids with carbon chain lengths of 16–18, such as stearic, oleic, palmitic and linoleic acids, are commonly used as ink collectors. Saturated fatty acid soaps usually have better ink collection while unsaturated fatty acid soaps have higher foam-

ing. To function effectively as ink collectors, fatty acids require the presence of moderate concentration of calcium ions such as at least 12 degree German hardness (dH) or approximately 200 p.p.m. as calcium carbonate. The calcium ions can be sourced from the paper fillers such as calcium carbonate, or from the addition of calcium chloride or oxide. To maximize the function of any source of calcium ions, it is important to maintain the flotation in alkaline conditions (>8 – 8.5), otherwise fatty acids precipitate. However, the presence of excess calcium ions in the system may cause fibre loss.

Nonionic surfactants Nonionic surfactants encompass a large number of synthetic chemicals of varied types and structures. Major types of nonionic surfactants include fatty ethoxylate, alkyl phenol ethoxylate and fatty acid alkoxyate. Cloud point and hydrophilic/lipophilic balance (HLB) value are two important terms used to describe a given nonionic surfactant. Cloud point is the temperature at which nonionic surfactants become separated from the solution. Below the cloud point, surfactant has higher foaming and above the cloud point, the foaming of surfactants decreases dramatically. HLB value is the ratio of weight percentages of hydrophilic to hydrophobic groups in the structure. Generally, for the same surfactant, the higher the HLB value, the higher the foaming ability, and the lower the ink collection ability. An effective nonionic flotation surfactant usually possesses the properties of good ink collection and adequate foaming.

Some of the most common nonionic surfactants used in flotation deinking are EO/PO copolymers, in

Table 4 Typical flotation de-inking surfactants

<i>Types</i>	<i>Name</i>	<i>Formula and structure</i>
Anionic	Fatty acid and emulsion	$CH_3(CH_2)_nCOOH$
	Fatty acid soap (stearic/palmitic/oleic acid and soap)	$CH_3(CH_2)_nCOONa$ $CH_3(CH_2)_nCOONa$
	Alkylbenzene sulfonate	$R-(C_6H_4)-SO_3Na$
	Fatty alcohol sulfate	$R-OSO_3Na$
	Fatty alcohol ether sulfate	$R-O-(CH_2CH_2O)_nSO_3Na$
Cationic	Dodecyltrimethylammonium bromide	$CH_3(CH_2)_{12}NH_4Br$
Amphoteric	Sulfobetaine	$RN^+(CH_3)_2(CH_2)_xSO_3^-$
Nonionic	Fatty alcohol ethoxylate	$R-O-(CH_2CH_2O)_xH$
	Ethoxylated alkyl phenol	$R-(C_6H_4)-O-(CH_2CH_2O)_xH$, $n = 8-9$
	EO/PO copolymers	$HO-(EO)_x-(PO)_y-(EO)_z-H$
	Fatty acid alkoxyate	$RCOO-(CH_2CH_2O)_xH$
	Alkyl phosphate ester	$(RO(CH_2CH_2O)_n)_2POONa$
	Fuel oil	$CH_3(CH_2)_nCH_3$
	Fatty oil alkyleneoxide derivative	

EO, Ethylene oxide; PO, propylene oxide.

which the hydrophilic part is EO (ethylene oxide) and the hydrophobic part is PO (propylene oxide). Alkoxylates of fatty alcohols or fatty acids containing both EO and PO units have been used as flotation surfactants.

As environmental regulations become tougher, de-inking mills tend to prefer to use surfactants that are easily biodegradable. Because of the difficulty of breaking down alkyl phenols in wastewaters, they are gradually being replaced by readily biodegradable products such as alcohol ethoxylates.

Flotation Recipes

The selection of optimal flotation chemistry recipes depends strongly on both ink properties and types of wastepaper. The flotation recipes that are commonly employed are summarized in Table 5.

Old newspapers Newsprint (100%) is often de-inked by washing. However, flotation can also be effective to remove newsprint inks with fatty acid/calcium ion chemistry. In the absence of calcium ions, the ink particles do not float using fatty acid collectors. The addition of calcium is indispensable for a fatty acid or a soap to function properly as a collector. Positively charged calcium ions are bonded to the fatty acid and to the negatively charged ink particles, and thereby promote ink flotation. Calcium ions (often as calcium chloride) should be added to the pulp simultaneously or before the fatty acid at a level of above 100–150 p.p.m. as calcium carbonate.

ONP/OMG mixture Ash plays a very important role in the flotation de-inking of newsprint. It is a common practice to include a certain per cent of old magazines (OMG) in old newsprint (ONP) for better flotation de-inking efficacy. Since OMG and mixed office waste (MOW) contain fillers such as calcium carbonate, the presence of these fillers in the wastepaper promotes ink flotation. This is because the fillers can provide the calcium ions needed by the fatty acids. Traditionally, the mixtures of ONP and OMG, usually in the ratios of 70 : 30 and 50 : 50, are de-inked by flotation at an alkaline pH using fatty acids or soaps. A significant improvement in ink removal of newsprint can also be achieved by adding clay to the pulper.

Mixed paper Most of the early plants used alkaline conditions to de-ink mixed wastepaper. However, there is a trend for modern de-inking mills to switch to neutral conditions. Fatty acids are commonly used in Europe and Asia and nonionic surfactants alone are commonly used in North America for de-inking mixed paper. However, fatty acids in combination with nonionic surfactants are found to be the most effective in removing both large and small ink particles.

Flexographic inks Flexographic inks are water-based inks and are difficult to de-ink using flotation due to the hydrophilic nature and very small size ($< 5 \mu\text{m}$) of the ink particles. Flexographic inks tend

Table 5 Typical flotation recipes of waste paper de-inking

Medium	Pulping			Flotation	
	Alkali and bleaching agent	Chelate or dispersant	pH	Collector and frother	Furnishes suitable for the flotation chemistry
Alkaline de-inking	NaOH Na ₂ SiO ₃ H ₂ O ₂	EDTA DTPA Phosphate	8.5–11.5	Fatty acids or soaps with calcium ions	100% ONP, 100% flexographic ONP/OMG
				Fatty acids or soaps	ONP/OMG, ONP/SOW, OMG trimming/MOW
				Fatty acids or soaps and nonionic surfactants	ONP/OMG, ONP/SOW, OMG trimming/MOW
				Nonionic surfactants	Sorted ledger, MOW, CPO
Neutral de-inking	NaOH (optional)	EDTA DTPA (optional)	5.5–8.0	Fuel oil and nonionic surfactants	100% flexographic ONP and OMG
				Fatty acids or soaps	
				Fatty acids or soaps and nonionic surfactants	MOW, sorted ledger, OMG trimming/MOW
				Nonionic surfactants	MOW, sorted ledger, OMG/MOW, CPO, manifold
				Fuel oil and nonionic surfactants	MOW, sorted ledger, OMG/MOW, toners
					Flexographic ONP/OMG

For abbreviations, see Table 1.

to redeposit on the fibres and may cause a dramatic brightness drop of the pulp. Similar to 100% newsprint, fatty acid soaps and calcium ions are found to be effective in removing flexographic inks.

Toner inks Xerographic paper and laser computer printout (LCPO) are frequently found in government publications and general office waste. The inks in these papers are thermoplastic powders or toners, and are firmly bonded to the fibres with a heat fusion printing process. The toner ink particles are hydrophobic, but their removal efficiency by flotation is poor compared with conventional inks since the toner inks are large in size and cannot be sufficiently detached from fibres in the pulper. Effective removal of toner inks can be realized using high consistency mechanical dispersion of the pulp with kneader and disperger followed by flotation using nonionic surfactants. Kneader and disperger assist flotation by improving toner-fibre detachment and by reducing the ink size distribution to a more floatable range.

Future Trends

Flotation de-inking is a complex separation process of inks and other contaminants from fibres. Due to economical reasons and strict environmental regulations, new materials used by paper manufacturers and new printing technologies, paper mills require environmentally benign de-inking technologies which can easily fit into the current de-inking system without extra capital investment.

In recent years, great progress has been made in flotation de-inking technologies with respect to flotation cell design, utilization of new surfactants and the understanding of de-inking chemistry. However, the rapid advances in printing, coating and other modifications of paper make de-inking more difficult. More effort is needed to understand the flotation behaviour of new types of wastepapers.

Flotation chemistry plays the most important role in determining the ink removal efficiency. Neutral flotation de-inking has become increasingly popular in the last 10 years. This is mainly because neutral de-inking has great potential to lower chemical usage and cost, to reduce water treatment cost, to improve product quality and paper machine runnability. Mills will benefit from switching from alkaline to neutral flotation de-inking. Since no caustic or silicate is added in the pulper, fibres are not yellowed or darkened. As a result, bleaching chemicals such as peroxide may not be required.

Enzymatic de-inking represents a new approach to modern paper-recycling mills. Extensive research has

been conducted to use enzymes to improve de-inking efficiency. The enzymes used included primarily cellulases, hemicellulases, amylase, lipase or resinase. Commercial application of enzymes to the flotation de-inking of wastepapers showed enhanced ink removal efficiency. Neutral pH de-inking further benefits the use of enzymes since it can improve ink detachment from the fibres and repulping efficiency. Since most enzymes work at acidic pH and lower temperature, enzyme manufacturers have to develop thermophilic and alkaline-stable enzymes to lower usage and enhance their effectiveness.

Introduction

The forensic biologist has traditionally used a large set of markers including blood group antigens and serum proteins to establish links between evidence and comparison samples. These markers are polymorphic and genetically determined. In 1985, a new technique was introduced which opened the door to the forensic use of deoxyribonucleic acid (DNA) technology: its inventor coined the term 'DNA fingerprinting'. Since then, DNA typing in this and many other forms has flourished and the forensic biologist now has access to a large variety of powerful techniques.

DNA and its Polymorphism

DNA is an extremely large linear molecule which stores genetic information in the form of a sequence of its constituent elements: the nucleotides. The DNA molecule is made up of two complementary chains or strands of nucleotides (Figure 1). There are four different nucleotides (symbolized by the letters A, C, T, G) whose chemical affinity determines the complementarity of the nucleotide sequences of the two strands of the DNA molecule. Nucleotides A and T, and G and C always face each other; as a consequence, the length of DNA fragments is usually expressed in 'base pair' (bp) units. This chemical affinity allows single strands of complementary DNA to hybridize to each other. Nucleotide chains are oriented, having so called 5' and 3' ends, and the two strands of DNA have an opposite orientation. The DNA synthesis occurs in the direction 5' → 3'.

The polymorphism within DNA resides partly in the existence of minor nucleotide sequence variations among different individuals at various locations (loci) in the DNA molecule, which has its counterpart in the polymorphism of the amino acid sequence of the proteins. The gene variants (the alleles) differ

in their sequence. However, a more extensive and DNA-specific polymorphism exists in the noncoding DNA: the tandemly repeated sequences. These polymorphic loci are DNA fragments, made up of a nucleotide sequence (the repeat unit), tandemly repeated like a series of identical beads on a necklace (Figure 1). The repeat unit can be from two to more than 100 nucleotides long. The polymorphism comes from the extreme variation in the number of repeats. The alleles differ then by their size (length polymorphism). This kind of repetitive sequence has been called minisatellites or also variable number tandem repeat (VNTR). There is a huge reservoir of polymorphism in these sequences and it is their potential use which has stimulated the development of the various DNA typing procedures.

DNA Typing Procedures

Any biological material containing DNA may be useful, including blood, sperm, saliva, hair, autopsy tissue, bone. All DNA typing procedures involve a DNA isolation step, which allows the elimination of substances such as proteins which can interfere in the sometimes delicate enzymatic steps involved in any DNA typing method.

The traditional way to prepare samples is to dissolve them in a sodium dodecylsulfate (SDS) proteinase K solution which lyses the cells and digests the proteins. The samples are then extracted with a phenol/chloroform mixture and the DNA is finally ethanol-precipitated and dissolved in the adequate buffer. Polymerase chain reaction (PCR) analysis requires minimal amounts of DNA so that it is possible to start with samples so small that they are unlikely to contain substantial amounts of interfering molecules. Simple boiling of the samples in the presence of a heavy-metal chelator (Chelex resin) is then usually sufficient as a preparation method.

Figure 1 Schematic description at four increasing levels of magnification for DNA and VNTRs.

Restriction Fragment Length Polymorphism (RFLP) Typing

The isolated DNA is reproducibly cut into fragments by the action of a sequence specific DNA cutting enzyme, a restriction enzyme (hence RFLP). The fragments, which can be more than 20 000 bp long, are then separated according to their sizes by electrophoresis on agarose gel. The DNA fragments are transferred to a nylon membrane to which they will remain attached but are still accessible for hybridization with a probe. This membrane will provide a replica of the electrophoresis product. Labelled pieces of DNA having a sequence complementary to the repetitive sequence to be detected (the probe) are added to the nylon membrane and hybridize to the appropriate DNA fragments. These can finally be detected by autoradiography with a film sensitive to the labelled probe (**Figure 2**). The DNA fragments to be detected will appear on the film as dark bands (**Figures 2** and **3**). Their position will be a measure of their size, which is itself proportional to the number of repetitive elements in the VNTR. A comparison with DNA fragments of known sizes allows an accurate size determination. This first probe can be stripped from the membrane allowing for reprobing with a second probe, etc. There is a large choice of VNTRs available for RFLP typing (**Table 1**). It is the same for restriction enzymes: but a few have found wider use because of their robustness and their ability to cut DNA into small fragments. These enzymes are *Hae* III, *Hinf* I, *Pst* I, *Alu* I and *Pvu* II, the first two being the most used. The labelling of the probe is traditionally done through the use of ^{32}P -labelled nucleotides. However, probes coupled to enzymes catalysing the production of a chemiluminescent substance allow detection limits as low as those obtained by radioactive means.

The probe can be designed so as to detect a single VNTR locus; it is then a single locus probe (SLP). If the individual has inherited DNA from his parents with a different number of repeats at the analysed VNTR, the result is in the form of two bands (heterozygote); otherwise, there will be a single band (homozygote). But since the repeat units of different VNTRs often have sequence similarities to each other, it is possible to detect a whole family of VNTRs at the same time provided a probe is used under conditions allowing hybridization with partially complementary DNA fragments. In this case we speak of a multilocus probe (MLP) and the result appears in the form of a set of bands with a very individual pattern similar to a bar code.

Polymerase Chain Reaction (PCR)

The advent of the PCR has dramatically enlarged the spectrum of methods available for DNA typing. The PCR is a DNA amplification method which cyclically reproduces the natural DNA replication. Each cycle consists of (1) a denaturation step where the two DNA strands are separated by heating, (2) an annealing step where, after cooling, short synthetic DNA strands (the primers) are hybridized on both sides of the DNA fragment to be amplified, and (3) an elongation step where a DNA polymerase adds nucleotides to the primers to synthesize the DNA strands complementary to the template DNA. The result of many cycles is millions of copies of DNA fragment delimited by the primers. The use of a heat-stable polymerase has rendered the whole process very easy and allowed it to be automated. The nature of a PCR makes it naturally extremely sensitive, with a theoretical detection threshold of one molecule. The primers allow the amplification to be highly specific and the amplification product can then frequently be detected using a simple nonspecific detection method, which

Figure 2 Schematic description of the main steps in RFLP typing.

Figure 3 Typical examples of RFLP typing of forensic cases. On the left: sexual assault case; St, size markers, V, victim, VS, vaginal swab (containing material from the victim and her assailant), S1, suspect 1, S2, suspect 2. On the right: paternity test with M, mother, C, child, F, putative father.

makes the whole analytical process convenient and rapid.

PCR and Dot-Blot Analysis

Many methodologies have been designed which make use of the main principle of a PCR. In forensic science, PCR was first used to analyse sequence polymorphisms such as the polymorphism of the *HLA-DQ α* locus. In that case, the alleles, which differ only by a few nucleotide changes, are identified after use of a PCR through hybridization with allele-specific

probes, using a reverse dot-blot format (Figure 4): the various probes are attached to a membrane strip, arranged as a series of invisible dots to which the amplification products can hybridize depending upon their sequence. Through the use of labelled nucleotides during the PCR, the genotype of the sample can be read through the appearance or not of coloured dots on the strip, at the position of each probe (Figure 4). In a way, the format is not very different from that of the strips for urine analysis so widely used in clinical medicine.

Amplification Fragment Length Polymorphism (AMP-FLP) Typing

Another use of a PCR has been the amplification of VNTRs to analyse their length polymorphism. However, the quite poor performance of PCRs in the amplification of large DNA fragments, such as those of the VNTR loci analysed through RFLP typing, has led to the search for smaller VNTRs (Table 1). By designing primers located on each side of a VNTR, it can be amplified by a PCR and the amplified fragments can be analysed by electrophoresis on agarose or polyacrylamide gels and compared to standards (Figure 4). While RFLP typing required the use of probes to detect specific VNTR-DNA fragments among thousands of other fragments, the amplification process here allows the use of nonspecific detection methods (ethidium bromide staining, silver staining) to make the bands visible. This kind of PCR-analysed VNTR polymorphism has been called amplification fragment length polymorphism (AMP-FLP).

Short Tandem Repeats (STR) Typing

The particularly high efficiency of PCR in the amplification of very small fragments has attracted attention toward a class of VNTRs made of very small repeats (di-, tri-, tetranucleotide repeats) (Table 1). They are sometimes called microsatellites

Table 1 Selection of some of the main DNA loci analysed by the various DNA typing methods

Locus	Corresponding probe	Chromosome location	Repeat unit length (bp)	Typing method used	Heterozygosity ^b (%)
—	33.6	1 ^a	37 ^a	multilocus RFLP	—
<i>D1S7</i>	<i>MS1</i>	1	9	monolocus RFLP	> 99

<i>HUMTH01</i>	—	11	4	STR	80

^aThese characteristics refer to the VNTR used as the multilocus probe.

^bHeterozygosity is calculated here as the percentage of apparent heterozygotes in the population (Caucasian in this case).

Figure 4 A PCR amplification for AMP-FLP typing (left) and reverse dot-blot analysis (right).

or short tandem repeats (STRs) and they are probably the richest class of polymorphic loci available. Their amplification conditions are simple and the size range of their alleles is usually narrow. They are then well suited to multiplexing; it is indeed easy to choose microsatellite loci and adequate primers so as to obtain amplified DNA fragments situated in well separated size ranges for each locus. Consequently a whole group of STRs can be amplified at the same time and analysed on the same gel. The small size of their repeat unit, however, is also a disadvantage. The various alleles only differ in length by two, three or four nucleotides. Such a separation power is only possible through the more complex technology of sequencing gel electrophoresis. However, the sequencing technology is undergoing constant improvement due to the challenge of the human genome sequencing project, and STR typing has benefited from the developments in that field such as fluorescent labelling and automatic sequencing.

Minisatellite Variant Repeat (MVR)-PCR

The polymerase chain reaction has made possible yet another powerful DNA typing method: MVR-PCR. This has been designed to reveal a polymorphism consisting of variations in the sequence of the repeat unit within some VNTRs. Instead of being a pure repetition of one repeat unit, some VNTRs are composed of combinations of two or more almost identical repeat units. It is easy to calculate that even with only two repeat variants a and b, the number of possible combinations of repeats is huge. The sequence of repeats is revealed through a process somewhat similar to the Sanger DNA sequencing method

(Figure 5). The PCR is carried out in parallel in two tubes in a mixture containing a primer complementary to a DNA sequence outside the VNTR and a low concentration of primer complementary to the repeat unit variant a. This set of two primers allows the multiplication of an array of all the possible fragment going from one end of the VNTR to every repeat a. In the second tube, the use of a primer complementary to the repeat unit variant b allows the multiplication of another array of all the possible fragments going from one end of the VNTR to every repeat b. An unequal amplification of the short versus long fragments is avoided through the use of a tag attached to the two alternative primers. This tag is a short strand of DNA. A fourth primer complementary to this tag is then used to allow the further amplification of the arrays of fragments. The content of the two tubes is then loaded on two adjacent lanes of an agarose gel. After electrophoresis, Southern blotting, hybridization with a probe for the VNTR and autoradiography, the result appears in the form of two parallel ladders of bands with fainter or missing rungs. For an individual, the result is indeed the sum of the results given by two VNTR fragments, those inherited from the mother and the father: at each repeat position in the VNTR the subject can have variant a twice, variant b twice, or a once and b once. These three possibilities can easily be coded by the numbers 1, 2, 3, allowing a simple digitization of the result (Figure 5). It is clear that the existence of more than two repeat variants makes the coding more complex and the system more informative but the principle remains the same. With MVR-PCR, there is no need to have carefully standardized electrophoretic conditions. Each

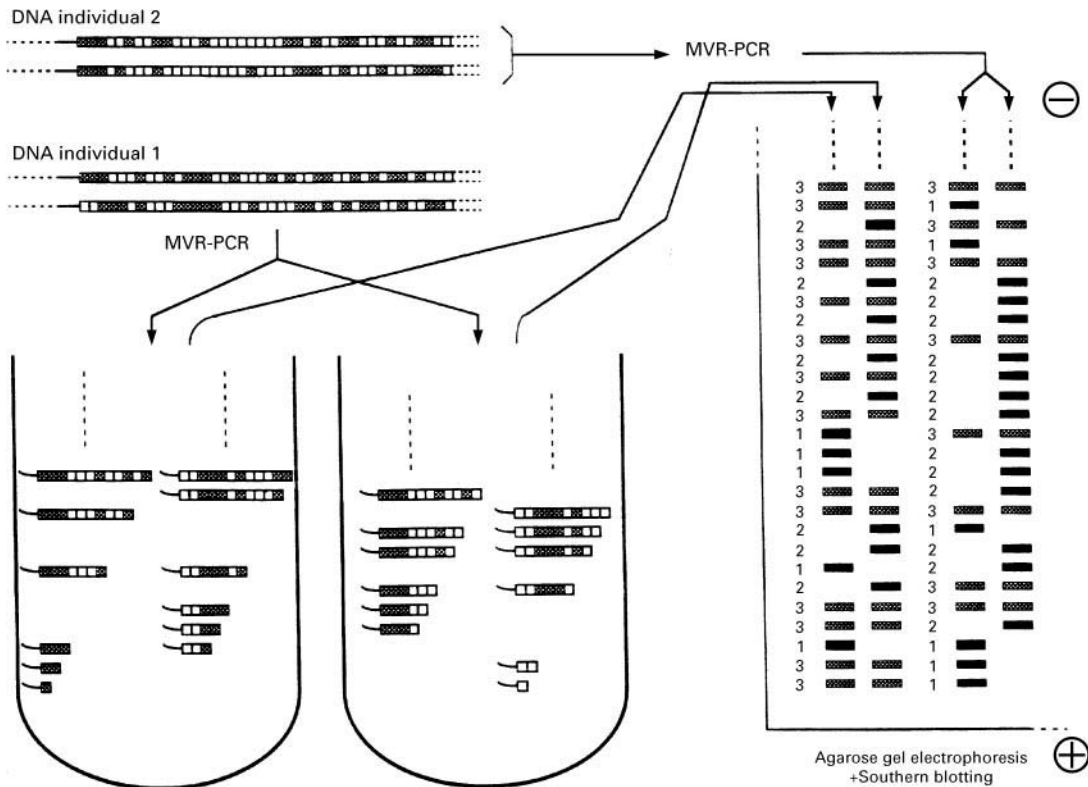

Figure 5 Schematic description of MVR-PCR.

result is literally read by itself, and different samples are simply compared at the level of their codes.

Other Methods

Other DNA typing methods have been developed or proposed, and still others are yet to appear. Two methods are worth mentioning. One is mitochondrial DNA (mtDNA) sequence analysis. A DNA sequence analysis after PCR amplification is a natural way to examine DNA polymorphism. However, because it is unable to reveal more than a few hundred base pairs at a time, and because of its complexity, it is not as attractive as the above-mentioned methods. However, it has been a precious tool in the analysis of mitochondrial DNA, which is a small piece of DNA, maternally inherited, present in all mitochondria. Part of it (the D-loop) contains a highly polymorphic sequence and its sequence determination is therefore very informative. Owing to the presence of more than 1000 copies in each cell, mtDNA analysis is very sensitive. Moreover, hair shafts, which do not contain nuclear DNA, are rich in mtDNA and are therefore amenable to genetic analysis.

The second method is polymorphic sequence-tagged sites (pSTS) analysis. This is a method designed to reveal single base pair changes. After a PCR amplification of the DNA fragment containing the

polymorphic base pair, a ligation assay is performed using an antigen-labelled primer and one of two biotin-labelled primers each being specific for one of the two possible alleles. In the presence of the corresponding sample allele, the biotin-labelled primer is ligated to the antigen-labelled primer. After capture of the product in microtitre plates coated with streptavidin (a binding protein for biotin), the presence of the antigen can be detected using a traditional immunoenzymatic method (ELISA procedure). The combined analysis of more than 15 such two-allele sites can reveal genotypes with frequencies below 10^{-6} . The most interesting features of this method are its technical simplicity and its straightforward interpretation (positive or negative readout) which make it particularly amenable to automation. It could reach its highest performance if all the loci could be analysed simultaneously within the same tube.

Applications

Deoxyribonucleic acid typing gained prominence from the start because of its identification power. It is the most powerful identification technique after fingerprint examination. It represents a big jump from the traditional protein polymorphism analysis where powerful identification could only be reached by the

sequential analysis of more than 20 polymorphic systems, each requiring its own analytical process. The improvement is particularly evident in semen analysis where the number of available polymorphic systems was extremely low. In RFLP typing, the analysed VNTR loci are so polymorphic that most of the possible genotypes have frequencies below 1%. It is then easy to calculate that the combined analysis of four such loci reveals genotypes with frequencies of the order of 10^{-8} . Both AMP-FLP typing and STR typing use smaller, less polymorphic and therefore less informative VNTRs, but a similarly high information yield can be reached by increasing the number of loci analysed.

Interpretation

Forensic identification is achieved through the demonstration of matching biological characteristics between evidence and comparison material. The matching is straightforward when discrete and well-identifiable alleles are analysed such as in the various methods derived from a PCR. However, in RFLP typing, a match is not always easy to establish. First there is the intrinsic difficulty of having to deal with alleles which cannot each be differentiated by electrophoresis. Indeed, because of the size range of the DNA fragments, the separation power of electrophoresis is insufficient to separate alleles differing in length by only one repeat unit. Two samples having bands at an identical position may in fact possess different alleles. Secondly, there is the possibility that a DNA sample originating from the same person as the comparison sample contains interfering molecules, leading to a different electrophoretic behaviour and shifted band positions. This bandshifting can only be demonstrated and evaluated through the use of proper controls (internal standards).

The next step in the interpretation is the evaluation of the power of the evidence. It is usually expressed as a ratio of the probability of the evidence under the hypothesis that the evidential material has the same source as the comparison sample and the probability of the evidence under the hypothesis that somebody else is the source of the evidence material. This ratio is normally inversely proportional to the frequency of the genetic characteristics detected in the adequate reference population. The determination of these frequencies is a difficult task. The extreme variability of the VNTR loci makes the gathering of genotype frequency data unrealistic. Statistically trustworthy frequencies would require the analysis of a huge number of individuals. It is thus necessary to rely on allele frequencies to calculate the genotype frequencies by multiplication. The frequency of genotype A_1A_2 at locus A is the product $2a_1a_2$ (with a_1 and a_2 being the

respective allele frequencies). The frequency of the combined genotypes at four loci is then $2a_1a_2 \times 2b_1b_2 \times 2c_1c_2 \times 2d_1d_2$. However, these multiplications can only be done under the assumption of statistical independence of the multiplied factors. This translates into certain assumptions related to the genetic independence of the analysed VNTR loci and to the genetic structure of the populations (Hardy-Weinberg equilibrium).

Controversy has arisen over the possibility of the existence of genetic substructuring within the populations. Some geneticists expressed concern that the frequency of a genotype A_1A_2 might have an apparent value using the general population database, but that the true frequency might be much higher owing to the high frequency of these specific alleles in a genetically distinct population subgroup. At the extreme, if alleles A_1A_2 only appear in this subpopulation where they have a frequency of 50% each, the detection of allele A_1 in a sample would make the detection of allele A_2 almost certain. Because of such effects, combined genotype frequencies could be underestimated by several orders of magnitude. The accumulating data suggest, however, that there is not much reason to worry about such effects. The VNTR loci are extremely polymorphic in every population studied and, for any given genotype constellation, there is an extremely low probability of having substantial frequency differences when calculating with one population data or another. Moreover, within the major races, the frequency distributions are very similar between different populations. And finally, forensic laboratories use very conservative approaches which always favour the accused at each interpretation step.

Paternity Testing

The identification power of DNA typing has naturally been used in paternity testing (Figure 3). But here the question relates to the transmission of genetic material from one generation to the other. Mutations which can cause apparent exclusions of true fathers then have to be taken into account. The polymorphism of the VNTRs is linked to an exceptionally high mutation rate. This mutation rate can be below 10^{-4} to more than 0.05 mutations, per meiosis for the most polymorphic loci such as *D1S7*. This has to be compared to the mutation rate of coding DNA sequences which is estimated to be around 10^{-5} for a 1000 bp gene. The calculation of probability of paternity has to integrate these mutation rates. But it remains true that the increased power of DNA typing has made paternity testing much easier and has allowed the solution of complex situations, such as the unavailability of the putative father, which sometimes remained unsolved with traditional typing.

Practical Use

In the real world of forensic science, there are practical contingencies which can be the source of difficulties or even interpretation errors. An important contingency is the quantity of the evidential material. Any living cell contains about 6 pg of DNA, and the main forensic DNA sources contain about 30 ng μL^{-1} (blood), 400 ng μL^{-1} (semen), 2 ng μL^{-1} (saliva) and 0–250 ng per hair root. As indicated in Table 2. RFLP typing would require at least a few microlitres of blood and the various PCR methods require about 0.05 μL . The theoretical PCR sensitivity of one molecule would suggest that less than 1 nL of blood should be sufficient. However, this does not take into account the potential loss during DNA isolation, or, more importantly, that one of the alleles may be absent or underrepresented in small samples containing only a few molecules, for simple stochastic reasons. As a consequence, it will not appear at the end of the process: a heterozygote will appear as a homozygote. In other words, there may be an allele drop-out.

Another important factor is the quality of the material. Although DNA is a robust molecule and usable DNA fragments have been recovered from thousand year old mummified bodies, it can very quickly be degraded into smaller fragments when exposed to humidity, heat or sunlight. With such degraded samples, DNA typing methods like STR typing, which analyse very short DNA fragments, may still be applied successfully. However, RFLP typing may be no longer possible. Or even worse, a DNA sample possessing a large and a small allele at a VNTR locus may have larger fragments which are too degraded to be detected while the smaller ones will have survived enough to give a detectable band. Here again, the result is an allele drop-out. That is why, in the usual procedure, a small portion of the sample is loaded on

a minielectrophoresis gel followed by nonspecific DNA staining. The examination of the intensity of the staining and the average size of the DNA fragments allows both quantitative and qualitative evaluation of the available DNA. The quality of the material can also affect RFLP typing through the inhibition of the restriction enzyme. One of the expected DNA fragments may appear at a position corresponding to a larger size than it should, because the enzyme has failed to cut the restriction site closest to the VNTR efficiently.

The experienced analyst usually has no problems avoiding interpretation errors arising from the above-mentioned situations or others (extra bands due to unsufficiently stringent hybridization, incomplete stripping, internal restriction site or bacterial contamination, missing bands due to blotting problems, etc.). However, without extensive controls, it may be difficult to prove the tentative explanation. And the limited amount of evidence material usually precludes repeating an analysis.

With PCR-derived methods, there are a few specific potential sources of error worth mentioning. The first is contamination. A PCR is so sensitive that inadvertent transfer of DNA from one sample to another, from laboratory personnel to the samples, etc., can happen and be unnoticed. The large-scale use of negative controls should reveal any such contamination. Moreover, the establishment of adequate laboratory design and use of pertinent working guidelines and decontamination procedures should prevent the occurrence of such damaging episodes. The second source of error is differential amplification. The trustful amplification of a heterozygote requires that the two alleles are amplified with the same efficiency, otherwise the result is an allele drop-out. Consequently, the conditions which lead to such differential amplification have to be established and the proper precautions must be taken.

Table 2 Main characteristics of the various techniques available for DNA typing

	<i>Amount of genomic DNA required</i>	<i>Ability to use damaged DNA</i>	<i>Probability of matching per locus analysed^a</i>	<i>Degree of automation possible</i>
RFLP typing with single locus probes	> 20 ng	—	< 1%	—
RFLP typing with multilocus probes	> 500 ng	—	< 10 ^{-7b}	—
PCR + dot-blot analysis (<i>HLA-DQα</i> typing)	< 1 ng	+	7%	+
AMP-FLP typing	< 1 ng	+	5–10%	+
STR typing	< 1 ng	+	2–10%	+
MVR-PCR	> 1 ng	+	< 10 ^{-6c}	+
mtDNA sequencing	≤ 1 ng	+	10 ^{-4c}	+
pSTS analysis	< 1 ng	+	40%	+

^aThe probability of matching (P_m) is the probability that two individuals taken at random have the same genotype. $P_m = \sum_{i=1}^n P_i^2$ where P_i is the frequency of the genotype for the analysed locus.

^b P_m is that for the whole set of loci detected by this probe.

^cThese numbers are estimates based on limited population samples.

The potent identification power of DNA typing makes the establishment of databases for the storage of DNA profiles possible and desirable. New profiles can be compared with stored profiles to identify criminals, link unsolved cases, etc. This necessitates a high level of standardization among the laboratories participating in the information exchange networks. They must at least analyse the same polymorphic loci and, for RFLP typing, they must use the same enzymes and similar analytical protocols. Because of the large choice of polymorphic loci and analytical methods, the minimum degree of coherence is not at all warranted unless a strong effort is made between the laboratories to reach a consensus. And a consensus is difficult to reach in a fast moving field where new technologies are constantly being developed.

There is no doubt that DNA typing is the 'safest' identification technique ever used in forensic biology. But, because of its power and its consequent impact in a courtroom, it is and will remain under intense scrutiny by the forensic and legal communities. Consequently, a lot of attention has been paid to quality control and proficiency testing. There is certainly the opportunity for future improvements and developments in this field.

Introduction

One of the earliest reports on DNA capillary electrophoresis (CE) was by Cohen *et al.* who demonstrated the high resolution of nucleosides and oligonucleotides, in the absence of a sieving gel, by simply trapping the analyte into sodium dodecyl sulfate (SDS) micelles. One year later, in 1988, the same author discussed the separation of DNA restriction fragments in a gel-free environment. The first reports on the use of polyacrylamide gel capillary columns to separate DNA with remarkable efficiency and resolution were presented the same year by Guttman *et al.* and Cohen *et al.* By 1989, gel-filled CE was already a well-established technique. These preliminary reports were then followed by a flurry of articles describing applications of capillary gel electrophoresis (CGE) to the separation of DNA restriction fragments. In spite of the high resolving power and efficiency offered by CGE in the analysis of nucleic acids (15–30 million plates per metre and a single-

base resolution for fragments ranging from 15 to more than 500 bases were reported), the difficulties of producing adequate gel-filled capillaries hindered their greater application. Heiger *et al.* proposed, as early as 1990, the use of polyacrylamide cross-linked with a very low or zero concentration of *N,N*-methylenebisacrylamide. Strangely enough, the revolution brought about by the use of polymer solutions as sieving matrices was only evident in 1991 as a result of the work of Guttman and Cooke and Grossman and Soane. Since then, hundreds of reports have demonstrated the advantages of performing DNA separations in a narrow fused silica capillary. Due to its high resolving power and quantitative capability, CE has been successfully applied to different kinds of DNA analysis, including the following: DNA sequencing, separation of restriction fragments, polymerase chain reaction (PCR) products and synthetic oligonucleotides.

Advantages of Capillary over Slab Gel Electrophoresis

For many years electrophoretic separations of DNA were carried out in slab gels. One of the main

Table 1 Typical field strengths applied in different DNA electrophoretic systems and analysis time

Separation system	Typical field strength ($V\text{ cm}^{-1}$)	Time
Agarose slab gel	5	Hours
Conventional polyacrylamide slab gel	8	Hours
Sequencing in thin polyacrylamide DNA slab gel	40	Hours
Capillary electrophoresis	300–700	Minutes or seconds

problems in electrophoresis is the dissipation of Joule heat created by the passage of current through the gel and the buffer solution. When the gel is not sufficiently and uniformly cooled, significant Joule heating occurs and temperature gradients are formed in the gel. The existence of a thermal gradient within the gel can cause band broadening and, eventually, DNA denaturation. An efficient way to overcome this problem is to carry out the separation in a fused silica capillary. At present, a typical capillary used for DNA electrophoresis has a 50–100 μm internal diameter (i.d.), a fused silica wall about 150 μm thick and a thin exterior coating (10 μm) of polyimide to provide flexibility. The high surface-to-volume ratio of the capillary leads to an efficient dissipation of Joule heat, which eliminates thermal and gravitational convection and allows the use of electric fields up to 700 $V\text{ cm}^{-1}$. **Table 1** shows typical values of field strengths applied in slab gel and CE and analysis times required by the different systems. As a result of the high field strengths typically used in CE, DNA separation 25 times faster than in slab gel electrophoresis is easily achieved.

Besides high speeds, another great advantage of CE is that DNA samples can be automatically loaded and the separated zones can be detected online by fluorescence or UV absorbance. Furthermore, the ease of online detection renders CE suitable for automation. The amount of samples typically loaded in CE is about three orders of magnitude lower (2–100 nL) than that used in slab gel electrophoresis, making the technique useful as a tool for the analysis of molecular biology products, which are often available only in minute amounts. Two types of online injection modes are performed in CE: electrokinetic injection and hydrodynamic injection. Electrokinetic injection is accomplished by placing one end of the capillary in the sample vial (which may contain as little as 2 μL of sample) along with a platinum wire electrode. The application of an electric field for a short time forces charged analytes to enter into the capillary through electrophoretic migration. DNA molecules, being negatively charged, are injected at the cathode end of

the capillary with the detector located at the anode end. In hydrodynamic injection, the capillary is placed in the sample vial and a sample plug is forced to enter into the capillary by applying, for a given amount of time, a differential pressure across the capillary. Both injection systems present advantages and disadvantages. Hydrodynamic injection avoids bias in the amount of the sample injected with the faster analytes injected in greater quantities and is more suitable for quantitation.

DNA Sieving Matrices

At neutral pH, DNA molecules being negatively charged migrate towards the anode when placed in a potential field. Their electrophoretic mobility is given by this simple expression:

$$\mu_e = \frac{q}{f} \quad [1]$$

where q is the net charge on the molecule and f is the molecular friction coefficient. DNA molecules in free solution adopt an open, extended conformation that allows solvent molecules to stream around each segment of the biopolymer equally. This implies that electrophoretic mobility of double-stranded DNA in free solution is independent of molecular size as both the net charge on the DNA molecule and its frictional coefficient increase linearly with the number of base pairs. A size-dependent separation of DNA requires the addition of a sieving medium to the running buffer. In slab gel electrophoresis, cross-linked polyacrylamide and agarose became commonly adopted in DNA work as support matrices due to their ability to reduce thermal and gravitational convection which would suppress the resolution. In addition, porous gels allow the passage of analytes providing the size-based separation of free-draining polyelectrolytes with nearly equal free solution electrophoretic mobility.

In a fused silica capillary the anticonvective role and the DNA-separating role of the electrophoresis matrix can be decoupled. In CE, even in the absence of a dense gel matrix, only very minimal thermal convection and diffusion of analyte molecules occur during electrophoresis due to the high electrical resistance of fused silica, resulting in low current generation. This feature allows the replacement of the gel with a solution of a linear neutral polymer. Most of the problems resulting from difficulties in the production of good quality gel-filled columns and with their limited lifetime have simply been overcome with the introduction of polymer solutions. Capillaries filled with linear polymers are relatively easy to prepare and use. Due to their low viscosity, solutions of polymers can be automatically pumped into the

Figure 1 Schematic representation of flexible polymer in solution. (A) dilute solution; (B) $c = c^*$; (C) semidiluted solution; (D) cross-linked chains. (Reproduced with permission from Heller C (1997) *Analysis of Nucleic Acids by Capillary Electrophoresis*. Wiesbaden: Vieweg.)

capillary before each run and removed at the end of the separation. The automatic replacement of the sieving matrix increases the capillary lifetime dramatically while reducing the need for sample clean-up.

Polymer Solutions as DNA Sieving Matrices

A number of polymers with different properties (such as molecular weight, hydrophilicity, chain stiffness) have been tested for their ability to sieve DNA molecules. Cellulose derivatives (hydroxyethyl, hydroxypropyl and hydroxypropylmethyl cellulose), uncross-linked polyacrylamide and polyacrylamide derivatives, dextran, polyvinyl alcohol, polyethylene oxide and polyethylene glycol represent some examples of sieving matrices used in CE with varying degrees of success.

According to Grossman and Soane, as size-dependent DNA electrophoretic separation requires the use of an entangled polymer solution. Coils of linear polymers, above a critical concentration, c^* , defined as the entanglement threshold concentration, begin to interact physically and form a physical gel with transient pores (Figure 1). The c^* concentration, characteristic for each polymer, can be experimentally estimated by measuring viscosity at different polymer

concentrations and finding the point of deviation from linearity on the viscosity vs. concentration plot. In an entangled polymer solution the DNA migration mechanism is similar to that observed in chemical gels (cross-linked gels), complicated by the dynamic nature of the DNA-polymer and polymer-polymer interactions. A high resolution can only be achieved in a rather narrow DNA size range (from 100 to 2000 bp).

When a polymer solution is far below the entanglement threshold concentration, polymer chains remain isolated in solution and, even if they transiently interact with DNA molecules, they do not form a porous network. However, DNA molecules larger than 2 kbp can be separated in ultradilute hydroxyethyl cellulose (HEC) solutions, although with a lower resolution. A new separation mechanism, transient entanglement coupling mechanism, was proposed to explain why the separation occurs in the absence of a sieving effect. When DNA and isolated polymer chains encounter each other, they become transiently entangled. DNA molecules, more stiff and extended in solution than polymer chains, drag the latter until they escape, slowing down their electrophoretic mobility. Large DNA fragments experience stronger entanglement interactions, therefore the time required to escape is size-dependent and DNA mobility becomes size-dependent. Below c^* , high molecular weight polymer chains provide a high speed separation of large molecules with a moderate resolution.

A polymer, in order to be a good sieving matrix for DNA in capillary electrophoresis, should meet the following requirements:

1. high water solubility;
2. low viscosity when used above its entanglement threshold concentration;
3. high chemical stability;
4. good sieving capacity;
5. UV transparency.

Most studies have demonstrated that the molecular mass of the polymer dissolved in the electrophoresis buffer influences the resolution and the interval of DNA sizes which can be separated. Polyacrylamide has, for a long time, been the matrix of choice for DNA sequencing and for dsDNA fragments up to 600 bp. Recently, several authors have replaced polyacrylamide with polymers obtained by radical polymerization of *N*-mono and di-substituted acrylamido derivatives. These polymers offer the advantage of being more resistant to alkaline hydrolysis than polyacrylamide. One of the most promising derivatives of polyacrylamide that has found application in CE is the *N,N*-dimethylacrylamide (DMA). Short chain poly(DMA) is produced by carrying out polymerization in organic solvents such as dioxane and *t*-

butanol or in the presence of a chain transfer agent. Besides optimal sieving capacity, this polymer possesses the unique feature of suppressing electroosmotic flow (EOF) even at 0.001% w/v concentration, allowing DNA separation to be carried out in uncoated capillaries. For large DNA (600 bp to 23 kbp) cellulose ethers, hydroxyethyl, hydroxypropyl, hydroxypropylmethyl (HPMC) and methyl cellulose (MC) have been used as separation media. Chemically modified cellulose derivatives are typically used to separate DNA fragments at concentrations of 0.2–1% w/v. Due to the fact that stiff and extended chains become entangled more easily than flexible random coil polymers, the operative concentration of cellulosic polymers is considerably lower than that used with polyacrylamides.

Influence of Electroosmotic Flow on DNA Separation

The most important characteristic of CZE capillary columns is associated with the chemical structure of the fused silica. The presence of several types of silanol groups (SiOH) on the inner surface of the capillary column which are weakly acid in character dramatically influences the CZE separation mechanism by inducing an electroosmotic component to the transport of ions during the analysis. Negative immobile charges on the wall surface generate an electric double layer at the silica–buffer interface consisting of an immobile layer of positive ions strongly adsorbed on to the surface and a diffuse layer extending into the liquid, which is made up of hydrated ions loosely and aspecifically bonded to the surface. When an electric field is applied tangentially to the surface, electrical forces acting on the mobile part of the diffuse double layer cause the movement of ions toward the oppositely charged electrode. The migration of these ions drags the surrounding solvent molecules; this overall movement of solution is known as EOF.

The control of the EOF and the suppression of wall adsorption is a key aspect in the achievement of successful DNA separations for two reasons: firstly, EOF can cause the extrusion of the sieving matrix during electrophoresis and secondly, immobile charges on the wall can electrostatically interact with ions which are oppositely charged. DNA molecules, being negatively charged under typical separation conditions, e.g. pH 8.0, 100 mmol L⁻¹ Tris–borate or acetate–EDTA buffer, are generally repelled by the wall. However, DNA sample contaminants and cationic intercalating dyes adsorb onto the wall, causing peak broadening and a reduction in efficiency.

There are a number of approaches to eliminate EOF and wall adsorption that act on the composition

Figure 2 Synthetic scheme for a polyacrylamide coating.

of the conducting medium. Most of these methods cannot be used for DNA since the operative pH and buffer ionic strengths that are typically used in the separation are chosen to maintain DNA molecules in their native, double-stranded helical conformation. Therefore there are severe limitations in the choice of buffer composition.

An effective way to suppress EOF which is fully compatible with DNA separation conditions is by coating the capillary inner surface with a neutral polymer. This can be accomplished in several ways:

1. by dynamic adsorption of water-soluble neutral polymers. These modifiers, generally contained in the running buffer, are strongly adsorbed to the wall by hydrogen bonding or hydrophobic interactions. Methylcellulose and poly(vinyl alcohol), for instance, have been used to produce a layer of high viscosity on the capillary wall which suppresses EOF.
2. permanent coating with small or large molecules chemically bonded to the surface silanols or immobilized as films of various thicknesses on the capillary wall. The simplest way to prepare these coatings is by bonding an organosilane bearing a reactive group that can be used, in a second step, to incorporate the organosilane into the polymer (Figure 2). Polyacrylamide, polyvinylpyrrolidone, and epoxy polymer coatings have been successfully prepared in this way.

Independently of the type of neutral polymer and of the mechanism which the polymer uses to bond to the wall, the viscosity in the thick layer of the double layer appears to govern EOF suppression. However, the nature of the interaction with the wall and the structure of the polymer play an important role on the coating stability.

Detection

One of the major advantages of CE is that the separated zones can be detected online. A short stretch (1–2 mm) of the polyimide coating is removed from the outside of the capillary and the UV transparent (UV cut-off of 170 nm) fused silica 'window' is directly placed inside the detector. Online detection prevents diffusion of separated zones resulting from flowing through the connections required by an off-column detection system. Nucleic acids are detected by UV absorbance at 260 nm or fluorescence. UV absorbance is simple and inexpensive; furthermore, this detection system allows the detection of nucleic acids based on their intrinsic UV absorbance without any need for intercalating dyes that can alter DNA electrophoretic mobility. The main drawback of UV absorbance detection in CE is its limited sensitivity resulting from the short path length available across the 50 μm capillaries typically used for DNA separation. Because of this limitation, laser-induced fluorescence (LIF) is currently employed for applications that require a higher sensitivity. An example is DNA sequencing where separated zones contain 1–10 attomoles of material.

Although an LIF detection system is more expensive and complicated to build than a UV absorbance

detector, its remarkable sensitivity renders this system the most popular method for DNA detection. The use of efficient fluorophores and laser excitation gives sensitivities up to six orders of magnitude greater than that typically achieved with UV absorbance. It has been demonstrated that bands containing 1 pg of DNA can be detected using ethidium bromide as fluorescent label. Several different labels with distinct spectral properties are available (FAM, JOE, TAMRA and ROX are four fluorophores used for DNA sequencing which has relatively widely spaced absorbance and emission spectra). These fluorophores are excited by the 488 nm and 514 nm lines of a common argon laser. Their $\lambda_{\text{ex,max}}$ varies from 550 to 610 nm whereas their $\lambda_{\text{em,max}}$ are between 520 and 605 nm.

Most of the efforts in developing LIF detection were carried out in the area of DNA sequencing by CE. The availability of good labelling strategies is at the heart of LIF detection development. Recently, energy transfer primers have been developed to increase sensitivity. These primers contain a common donor dye at the 5' end and an acceptor dye about 8–10 nucleotides away. The presence of a common donor allows the use of a single laser at 488 nm to excite all four fluorophore pairs efficiently.

Applications

The advantages of DNA CE over slab gel are such that an increasing number of molecular biologists around the world are beginning to apply this rapid and efficient technique to DNA mapping and sizing separations of medical and genetic interest.

Figure 3 Electropherogram demonstrating the efficient separation of a DNA molecular mass marker containing a mixture of fragments from cleavage of plasmid pBR322 with restriction endonuclease HAE III. Buffer 100 mmol L⁻¹ Tris-borate, 2 mmol L⁻¹ EDTA, pH 8.2. Temperature: 25°C; injection: 5 s at 1 kV; separation 200 V cm⁻¹.

Restriction Endonucleases and DNA Digests

Most work in CE literature has involved separating DNA restriction digests. The discovery of enzymes capable of recognizing and cutting a particular short sequence of base pairs (usually 4–8 bp long) in a double-stranded DNA molecule has been of fundamental importance in molecular biology. Restriction enzymes are used to compare near-similar DNA molecules by cutting them into smaller fragments which differ in length or sequence. Restriction digests such as Φ 174-HaeI-II, pBR322 HaeIII and pBR322 MspI, containing fragments in the size range from 50 to 1550 bp, have been separated by CE. Larger DNA fragments, from 125 to 23 130 bp, are usually generated with λ -HindIII. These restriction digests are relatively inexpensive, can be obtained at high concentration in a purified form and contain fragments of known size. They are often used in CE to test the separation efficiency of a given separation system (Figure 3).

Polymerase Chain Reaction

Polymerase chain reaction (PCR) is a molecular copying process that allows the amplification of the quantity of DNA available for a given test. Using a three-step temperature cycle, PCR allows specific regions of DNA to be amplified to a detectable level. The analysis of PCR products requires the ability to separate the target sequence from nonspecific prod-

ucts that may result from the use of nonoptimized conditions or from overamplification. CE has been successfully used for quantification and sizing of amplified products. Given its small sample requirements, CE can detect PCR products at a low cycle number using LIF, providing an efficient tool to evaluate PCR reaction parameters. Many of the separations which can be carried out on a slab gel have been successfully performed in CE. Some of the most significant papers on separation of PCR products by CE are reported in Table 2.

Capillary Sequencing

The first separations of DNA sequencing fragments by CE were reported in 1990 by groups at DuPont, Utah, Wisconsin, Northeastern and Alberta. DNA sequencing involves the separation of a set of single-stranded fragments differing by one nucleotide in length which share a common starting point and terminate randomly at a particular base. Since 1977, two methods have been developed and refined to sequence DNA fragments up to 500 bp. They are based on nucleotide-specific chemical cleavage or on the use of chain-terminating inhibitors of DNA polymerases (dideoxynucleotides -ddNTP-). Almost all DNA sequencing reactions nowadays are carried out according to the enzymatic protocol of Sanger. DNA sequencing provides the ultimate tool in the detection of DNA sequence variation. However, for measuring variations in large DNA regions it is necessary first to

Table 2 Application of PCR product analysis by CE

Type	System examined	PCR product size (bp) (resolution needed)

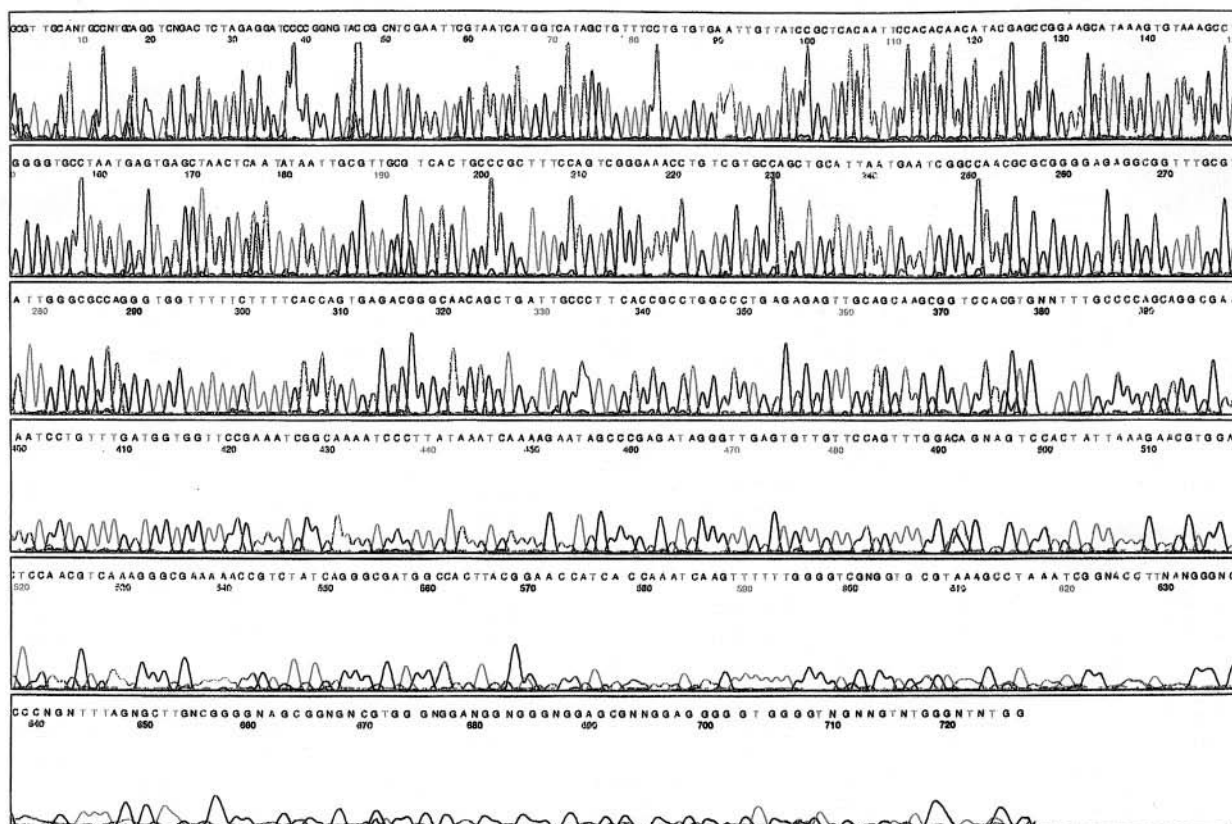

Figure 4 (See Colour Plate 76). Four-colour M13mp18 sequencing separation at 42°C. The separation of DNA sequencing fragments was performed in a 6.5% poly(dimethylacrylamide) (98 kDa) solution (75 cP) in 100 mmol L⁻¹ TAPS buffer (pH 8.0) containing 8 mol L⁻¹ urea. A 50 µm i.d. bare silica capillary, 51 cm long (40 cm to the window) was used. DNA was electrokinetically injected for 20 s at 60 V cm⁻¹, and the fragments were separated for 125 min at 160 V cm⁻¹. Reproduced from Madabhushi (1998), *Electrophoresis* 19: 224–230, with permission Wiley–VCH.

subdivide the region into smaller sections of about 400 bp. Hence, large numbers of sequencing reactions must be performed in each sample. To become applicable for screening purposes, DNA sequencing requires dramatic improvements in speed. CE provides a tool to increase sequencing rates significantly; at present, over 700 bases of sequence are routinely generated in a 2 h separation, and occasionally runs of 1,000 in 135 min have been generated. **Figure 4** shows a four-colour M13mp18 DNA sequencing separation.

Unlike in slab gel, where the four sets of A, C, G and T terminated fragments run in parallel in four different lines, in CE it is more convenient to run the four sets of fragments in the same capillary because this eliminates capillary-to-capillary variation in the migration velocity of different fragments. Different strategies have been developed to accomplish this goal, making use of four different labels with distinct spectral properties. Several labels, such as FAM, JOE, TAMRA and ROX, are available for sequencing. Some authors have reported the use of primers marked with different fluorophores whereas others

have suggested the association of a particular dye to a specific ddNTP chain terminator. In one approach, fluorescence was excited with two lasers, collected with a single microscope objective and discriminated with a filter wheel. Alternatively, a single laser-excited fluorescence and a two-channel directly reading fluorescence detector were used to discriminate fluorescence between the dyes.

A number of capillary array electrophoresis instruments with UF detection have recently become commercially available. These instruments have great potential for all those involved in the human genome project. In capillary array electrophoresis, many capillaries (typically six arrays of 16 capillaries) are set in parallel allowing parallel separations to be run as in slab gel but offering the advantages of analysis speed and automation typical of capillary electrophoresis.

Mutational Analysis

Detection and localization of single-base differences in specific regions of genomic DNA are of primary importance in the analysis of mutations associated

Figure 5 CZE analysis of mutant MV1 in exon 1 of the CFTR gene. The panel shows a run at a constant temperature plateau of 65 °C. Inset: run in a 65–67 °C temperature gradient, with a slope of 0.1 °C min. Sample injection: electrokinetic, 3 s at 4 kV. Reproduced with permission from Heller (1997) *Analysis of Nucleic Acids by Capillary Electrophoresis*. Viesbaden: Vieweg.)

with human disease. The methods used to detect point mutations exploit sequence-dependent variations in base-pairing which cause differences in conformation and lead to altered electrophoretic mobilities. Differences in melting behaviour of duplex molecules are the bases for separation of DNA sequence variants by electrophoresis. By running the separation under a temperature-programmed gradient (TGCE or thermal gradient capillary electrophoresis), a local loss of interstrand base pairing is induced, generating DNA molecules with a conformation very different from the normal worm-like rods. This allows the separation of molecules according to their melting characteristics and the detection of deviations from a wild-type sequence (Figure 5). In CE, the denaturing temperature gradients can be generated internally via ohmic heat produced by voltage ramps. The temperature increase linked to voltage ramps inside the capillary can be predicted as it depends on capillary diameter, its total length, the electric current values linked to a given applied voltage, the buffer electric conductivity and its coefficient of thermal conductivity. With the help of appropriate software, given these input parameters it is easy to assess dependence of

temperature on voltage ramps. A voltage gradient is then generated during the run, taking into account the melting profiles of the amplified fragments that can be predicted by the dedicated software of Lerman and Silverstein.

Future Developments

Looking to the future, we can expect new developments in instrumentation and technology. Another promising area is micromachining technology which has found widespread use in electronic and mechanic engineering, and is now increasingly applied to analytical chemistry and biotechnology. Photolithography and chemical etching techniques have been combined to create the field of micromachining in which three-dimensional microstructures have been fabricated on a micrometer scale. Electrophoresis on a chip has been successfully used for the separation of oligonucleotides, DNA restriction fragments and PCR products. In these microchip systems, fluid flow and reagent mixing are achieved using electrokinetic transport phenomena. Future developments can also be expected in this last area.

Introduction

The primary ingredients of a detergent are the surfactants, whereas *builders* provide the necessary backbone. The maximum efficiency of surfactants is achieved when the hardness in water is removed. Builders provide this essential function of water softening, primarily by means of ion exchange. Although the performance of surfactants is directly dependent on the efficacy of the builder, the consumer rarely notices the importance of the latter. The development in detergent technology during the last decade has been to improve the property of ion exchange that can lead to enhanced washing power of the detergent, while considering other factors such as environmental concerns and cost. This has been largely due to the development of ion exchange materials and molecular sieve type materials that have been used in detergent formulations as builders. Laundry detergents have a yearly \$4.4 billion market alone in the United States, shared equally by the liquid and powder detergents. A typical detergent composition is shown in **Table 1**. In today's detergents, builders constitute about 6–25 wt% of liquid detergents and about 20–55 wt% of powder detergent formulations. Thus builders play a significant role in the detergents market.

Until the early twentieth century, cleaning products were essentially soaps, i.e. sodium salts of natural fatty acids. The surfactants in the first synthetic detergents were short chain alkyl naphthalenesulfonates, which were followed by long chain alkyl benzenesulfonates (ABS). ABS were prepared by alkylation of benzene with propylene tetramer followed by

sulfonation. Although ABS had very good cleaning properties, they were non-biodegradable and their accumulation in the environment caused foaming in sewage treatment plants and rivers. Hence ABS were replaced by their straight chain analogues, linear alkylarylsulfonates (LAS) in 1965. Surfactants can be broadly classified as anionic, cationic and non-ionic. Today's detergent formulations contain mainly the anionic surfactants and a lesser amount of non-ionic surfactants. Cationic surfactants have very small market share compared to the anionic and non-ionic materials. The use of non-ionics is increasing in liquid detergents as they offer greater stability and formulation flexibility. Whereas the main function of builders is to provide water softening capability and alkalinity, they also serve other important functions as dispersants, antiredeposition agents, and anticorrosion, bleach stabilization and processing aid. **Figure 1** illustrates the various important functions played by zeolites in the washing process. Introduction

The primary ingredients of a detergent are the surfactants, whereas *builders* provide the necessary backbone. The maximum efficiency of surfactants is achieved when the hardness in water is removed. Builders provide this essential function of water softening, primarily by means of ion exchange. Although the performance of surfactants is directly dependent on the efficacy of the builder, the consumer rarely notices the importance of the latter. The development in detergent technology during the last decade has been to improve the property of ion exchange that can lead to enhanced washing power of the detergent, while considering other factors such as environmental concerns and cost. This has been largely due to the development of ion exchange materials and molecular sieve type materials that have been used in detergent formulations as builders. Laundry detergents have a yearly \$4.4 billion market alone in the United States, shared equally by the liquid and powder detergents. A typical detergent composition is shown in **Table 1**. In today's detergents, builders constitute about 6–25 wt% of liquid detergents and about 20–55 wt% of powder detergent formulations. Thus builders play a significant role in the detergents market.

Until the early twentieth century, cleaning products were essentially soaps, i.e. sodium salts of natural fatty acids. The surfactants in the first synthetic detergents were short chain alkyl naphthalenesulfonates, which were followed by long chain alkyl benzenesulfonates (ABS). ABS were prepared by alkylation of benzene with propylene tetramer followed by

sulfonation. Although ABS had very good cleaning properties, they were non-biodegradable and their accumulation in the environment caused foaming in sewage treatment plants and rivers. Hence ABS were replaced by their straight chain analogues, linear alkylarylsulfonates (LAS) in 1965. Surfactants can be broadly classified as anionic, cationic and non-ionic. Today's detergent formulations contain mainly the anionic surfactants and a lesser amount of non-ionic surfactants. Cationic surfactants have very small market share compared to the anionic and non-ionic materials. The use of non-ionics is increasing in liquid detergents as they offer greater stability and formulation flexibility. Whereas the main function of builders is to provide water softening capability and alkalinity, they also serve other important functions as dispersants, antiredeposition agents, and anticorrosion, bleach stabilization and processing aid. **Figure 1** illustrates the various important functions played by zeolites in the washing process. softened by builders, would react with the anionic surfactants and make them insoluble, thereby rendering them inefficient.

Development of Today's Builders

The earliest builders consisted of sodium carbonate and sodium silicate. Although inexpensive, the disadvantage of using these as water softeners is that they form sparingly soluble precipitates that deposit on fabrics and cause incrustation. In the 1950s, these builders were replaced by a complexing agent, sodium diphosphate. However, it was found that diphosphates also had similar shortcomings of forming precipitates. These drawbacks were overcome by introduction of sodium triphosphate (STP) and sodium tripolyphosphate (STPP) in the early 1960s. STP and STPP act as sequestering agents, which trap calcium and magnesium ions in the water very efficiently, forming water-soluble complexes. They also provide other functions like loosening the bond between soil and fabrics and buffering capacity. However, due to their nutrient value, the phosphates caused excessive fertilization and growth of algae in lakes and slow-flowing rivers, a phenomenon more commonly known as eutrophication. Nitrilotriacetic

acid was introduced in some countries as an STPP substitute, but was withdrawn after concern about its toxicological properties. In the 1970s, the aluminosilicate zeolite A, was introduced. The aluminosilicates differ from the STPP builders in that they are water insoluble and the mechanism of removal of the calcium and magnesium ions from the water is ion exchange instead of complexation. Usually they are used in conjunction with sodium

Figure 2 Water hardness distributions. CaCO_3 (ppm): \square , < 90; \square , 90-270; \blacksquare , > 270. (After Showell, with permission from Marcel Dekker.)

carbonate and polycarboxylates or citrates. Today in countries like the United States, Japan and some Central European countries, zeolites have almost completely replaced phosphates in detergents.

Builders for Water Softening

The percentage of builders in detergents depends on factors like water hardness, wash temperature and wash time. The dissolved inorganic salts of calcium and magnesium impart hardness to water. For the washing process to proceed effectively, it is important to remove the hardness ions in the water and replace them with sodium ions, rendering softness to the water. Thus the builder must exhibit high capacity for selective removal of these ions from water. The hardness level of water is different in different countries, leading to slight differences in detergent formulations. For example, water in Japan has relatively low hardness, typically less than 90 ppm CaCO_3 , whereas in the United States it is of low-to-intermediate hardness. The water in Western Europe has very high hardness (greater than 270 ppm CaCO_3 in 42% of the region) (Figure 2).

Phosphates ruled the detergent world until the introduction of inorganic builders. They are still widely used in a significant part of the world, e.g. Eastern Europe, Southern Asia, Africa, Australia and Latin America. We will discuss the phosphates briefly before going into detail on zeolites as detergent builders. We will also include some other inorganic silicate builders that may have impact on the detergent industry of the future. The main focus will be on the ion exchange properties of the materials, particularly zeolites.

Phosphates

Phosphates are excellent chelating agents and work by a sequestering mechanism, i.e. as previously mentioned, by trapping the calcium and magnesium ions and forming water-soluble complexes. A chelating agent possesses multiple sites with lone-pair electrons that are available to interact with corresponding electron-deficient coordination sites on metal ions like Ca^{2+} and Mg^{2+} ions. The chelation is reversible and the strength of chelation is indicated by the equilibrium constant, also known as a stability constant. The chelation proceeds in a stepwise manner between metal ions, I, and chelating agent, C. For a divalent cation it is a two step process given as:

The overall stability constant, K , is the product of the stability constants for each step ($K_1 \cdot K_2$). The log K values for stability constants of polyphosphates for binding of Ca^{2+} and Mg^{2+} ions are fairly high (5.2 and 5.7, respectively) at $> \text{pH } 9$. Hence, under normal washing conditions, STPP shows excellent sequestering capacity for both calcium and magnesium ions in solution. The binding capacity of STPP is fairly high, 158 mg CaO g^{-1} at 20°C and 113 mg CaO g^{-1} at 90°C . As the phosphates and the calcium and magnesium chelates formed are water soluble, the removal is very fast. In addition to water softening, after removal of the soil, they offer the function of suspending soil by electrostatic repulsion. They do not provide as high buffering capacity/alkalinity as sodium carbonate or sodium silicate. The low capacity of STPP to absorb non-ionic surfactants limits its use in the new compact detergents where considerable amounts of the latter are used. Efficiency and low cost are the biggest advantages of STPP. In many countries, where phosphates are not banned for environmental reasons, STPP is still the major player in the detergent builder market.

Zeolite A

The need for a substitute for STPP led to development of zeolites as detergent builders. Among the aluminosilicates, zeolite A is most preferred because of its high ion exchange capacity (170 mg CaO g^{-1}) and low cost of manufacturing. As opposed to chelation by STPP, zeolite A removes hardness of water by means of ion exchange, a process we will discuss in more detail in further sections. Another important difference that zeolite A exhibits from STPP is the selectivity for removal of divalent ions. STPP simply chelates both the Ca^{2+} and Mg^{2+} ions non-selectively from water. Zeolite A being a molecular sieve, shows higher selectivity toward Ca^{2+} ions over Mg^{2+} ions due to high hydration of Mg^{2+} ions. This is advantageous, as studies have indicated that the presence of a certain level of Mg^{2+} ions in fact improves the detergent performance. The ion exchange kinetics are strongly dependent on the wash temperature, and hence zeolites tend to be more effective at higher wash temperatures.

In addition to these properties, zeolite A offers other functionality to the detergents. It shows adsorption characteristics that are pH dependent. At pH 10, which is the pH during a normal wash, there is minimal adsorption of anionic or cationic surfactants, leaving them available for the soil removal. As the pH drops during the rinse cycle, the adsorption tendency of zeolites increases, leading to adsorption of colloiddally dispersed soil particles by heterocoagulation. Thus zeolites act as anti-redeposition

agents, minimizing fabric incrustation. In a mixed wash of coloured and white clothes, zeolite A suppresses the dye transfer from coloured to whites prohibiting staining. Zeolite A will ion-exchange trace metal ions such as Cu^{2+} , Zn^{2+} , etc. as well as remove them by the surface deposition of basic salts. As these metal ions are often responsible for decomposition of bleaches, use of zeolite A leads to an increase in the bleach performance. The only major shortcoming of zeolite A over STPP is the slower rate of ion exchange at low temperatures. This is often overcome by use of a soluble complexation agent, like citrate or a polycarboxylate. The complexation agent acts catalytically. The soluble complexation agent binds reversibly with the Ca^{2+} ions of the precipitate (either by ion exchange or by chelation), making them soluble. These solubilized Ca^{2+} ions are then readily exchanged by zeolite, making the complexation agent free for more transport. Usually about 2–8% of polycarboxylates are used as co-builders to enhance the performance of zeolite A.

Zeolite MAP

Other than zeolite A, zeolite P and in a few cases zeolite X are the only important zeolites that have been considered for detergent applications. Zeolite MAP, the maximum aluminium P which is a synthetic gismondine, is an improved version of zeolite P. In addition to the high binding capacity ($\sim 160 \text{ mg CaO g}^{-1}$), zeolite MAP has several distinct advantages over zeolite A. First, it enhances the stability of the sensitive and environment friendly bleaching agent, sodium percarbonate. Sodium percarbonate is sensitive to moisture present in the detergent formulation. The low mobility of water in the zeolite MAP structure imparts more stability to the water-sensitive bleach. Secondly, it exchanges calcium ions more rapidly and more selectively. Especially at low temperatures, the ion exchange kinetics are considerably faster than those of zeolite A. Finally, zeolite P exhibits higher liquid carrying capacity, e.g. for carrying non-ionic liquid surfactants, allowing free-flowing powder at higher liquid loading. With all these advantages, zeolite MAP is replacing zeolite A in more and more detergent formulations.

δ -Disilicate

Amorphous sodium silicates were among the earliest compounds that were used as builders. These compounds remove the water hardness by sequestering Ca^{2+} and Mg^{2+} ions, but form insoluble precipitates. Therefore amorphous silicates are used only in small proportions (0–3 wt%) mostly as a co-builder in the zeolite A builder systems. Here they provide a source of alkalinity and show selectivity towards Mg^{2+} ions. In contrast with amorphous silicates, layered silicates are crystalline and work by an ion exchange mechanism. These are polymeric crystalline materials, which have a layered structure. The monovalent metal ions (Na^+) in the interstices can be easily exchanged with divalent ions in solution and are responsible for the ion exchange capacity of the material. δ -Disilicate, which has the empirical formula $\text{Na}_2\text{Si}_2\text{O}_5$, is an anhydrous alkali silicate that is most important for its ion exchange properties. The formation of δ -disilicate is not thermodynamically favoured over the corresponding α - and β -phases; hence production requires a specialized high-temperature crystallization process. The δ -disilicate has a very regular structure (Figure 3) as opposed to the amorphous silicates.

The δ -disilicate does not have a thermodynamically stable structure in aqueous media. It disintegrates slowly into monomeric sodium silicate, commonly known as water glass solution but this process is much slower than the ion exchange kinetics. The hardness ions of water replace the sodium ions in the δ -disilicate interstices and give stability to the framework. During the wash cycle, the pH of the solution is generally maintained at a high level, and the ion-exchanged disilicate is stable. As the pH drops in the rinsing cycle, the Ca^{2+} and Mg^{2+} ions are released as silicates and the disilicate disintegrates into the wash water. The size of these insoluble calcium and magnesium silicates formed is small and does not cause incrustation.

The δ -disilicate is characterized further by its multi-functionality in detergent building. It is a very good source of alkalinity and has the high buffering capacity required for the washing process. It exhibits high adsorption capacity for the non-ionic surfactants. Its mild desiccant properties and ability to combine with heavy metal ions make it compatible with unstable bleaches like sodium percarbonate. This imparts good storage stability to the detergent formulation and allows the use of environmentally friendly bleaches. Once again, due to cost considerations, δ -disilicate cannot completely replace zeolite A at this point, but it certainly has great potential to act as a supplement to the zeolite A systems.

Figure 3 Polymeric structure of δ -disilicate. ●, sodium; ▴, SiO_4 tetrahedra.

Zeolites: Synthesis, Structure and Ion Exchange

Aluminosilicates are denoted by the general formula $M_{x/n}[(AlO_2)_x \cdot (SiO_2)_y] \cdot wH_2O$ where M is the cation of valence n , w is the number of water molecules and y/x usually has values of 1–5 depending upon the structure. The sum $(x + y)$ represents the total number of tetrahedra in a unit cell and the formula within parentheses represents the framework composition. The cation M , which functions as a charge balance in various solids, can be exchanged depending upon the equilibrium constant and this property finds use in several applications including catalysis, wastewater treatment, treatment of radioactive waste and in our context, detergents.

There are around 80 species of natural zeolitic minerals and about 150 types of synthetic zeolites. Of these, only a few have practical significance and a very few among them have importance in detergents. The synthetic zeolites, mainly zeolite A, and to some extent zeolite P and zeolite X are used in detergent formulations, mainly as ion exchangers.

Synthesis of Zeolites

Zeolites are normally synthesized in the sodium form. Most of the crystalline sodium zeolite is produced by crystallization from sodium aluminosilicate gels at a temperature below 150°C. The properties of the product zeolite depend greatly on the gel preparation and it is therefore a key step in zeolite preparation.

In a typical process for the synthesis of zeolite A, sodium silicate and sodium aluminate solutions are first mixed together. The resulting aluminosilicate is precipitated and crystallized hydrothermally to obtain the zeolite. Seed crystals of zeolite A are often used to obtain crystalline zeolite A in high selectivity. The crystallized zeolite is then washed, filtered and dried. The usual gel preparation temperature is 50–80°C and the temperature during crystallization is slightly higher 80–90°C. The time required for gel preparation may vary from 0.5 to 1.5 h, whereas 1–2 h is necessary for the crystallization. Optimizing the following variables controls the product quality: mixing sequence, speed of agitation, seed crystals, aging time and temperature. The desired properties for optimum detergent application are small particle size (typically < 10 µm), narrow particle size range, poor adhesive capacity (achieved by having crystalline material), high calcium binding power and good wettability.

Structure of Zeolite A

The structure of the crystallized zeolite A is quite unique. It is classified as a type 3 zeolite, for the

Figure 4 Structure of zeolite A.

interconnecting system is a double four-ring or an octahedron. The structure can be described in terms of two types of polyhedra; one is a simple cubic arrangement of octahedron or α -cage and the other is a truncated octahedron of 24-hedron or β -cage as shown in **Figure 4**. The cubic α -cages ($Al_4Si_4O_{16}$) are placed in the centres of the edges of a cube in the truncated octahedra. These α -cages connect the β -cages, creating a three-dimensional structure having pores of size 4.2 Å. Each corner of the cube (α -cage) is occupied by the truncated octahedra (β -cage) enclosing a cavity with a free diameter of 6.6 Å. The centre of the unit cell is a large cavity, which has a free diameter of 11.4 Å. A unit cell of zeolite A contains 24 tetrahedra; 12 each of AlO_4 and SiO_4 . A fully hydrated zeolite A contains 27 water molecules per unit cell. The theoretical Si/Al ratio in zeolite A is 1 but in many preparations the Si/Al ratio is slightly less than 1.

Structure of Zeolite MAP (Synthetic Gismondine)

Zeolite MAP is a type 1 zeolite, meaning that the interconnecting units are single four-ring units (also known as S4R). The eight-membered rings are interconnected by S4R units as shown in **Figure 5**. The interconnecting chains run parallel to both X- and Y-axes, creating a three-dimensional channel system. The mean free openings of the pores are 3.1×4.5 Å and 2.8×4.8 Å. The structure is somewhat flexible, as the connecting S4R units are two-dimensional. Due to this flexibility, slight structural differences are observed by dehydration of the zeolite. MAP has a Si/Al ratio of 1. This high aluminium content leads to a higher negative charge in the crystal lattice and therefore it has the highest theoretical ion exchange capacity.

Theory of Ion Exchange in Zeolites

The ion exchange process may be represented by the following equation:

Figure 5 Structure of zeolite MAP (synthetic gismondine).

where x and y are the charges of cations A and B and the subscripts z and s refer to the zeolite and solution, respectively. The equivalent fractions of the exchanging cation in the solution and zeolite are defined by:

$$A_s = \frac{xm_s^A}{xm_s^A + ym_s^B} \quad [4]$$

$$A_z = \frac{\text{number equivalent of exchanging cation A}}{\text{total equivalent of cations in the zeolite}} \quad [5]$$

where m_s^A and m_s^B are the molalities of the ions A and B respectively, in the equilibrium solution; also $(A_z + B_z) = 1$ and $(A_s + B_s) = 1$. The ion exchange isotherm is a plot of A_z as a function of A_s at a given total concentration in the equilibrium solution and at constant temperature. The preference of a zeolite for one of the two ions is expressed by the separation factor, α_B^A , defined by:

$$\alpha_B^A = \frac{A_z B_s}{B_z A_s} \quad [6]$$

If ion A is preferred, then α_B^A is greater than unity. The separation factor depends on the total concentration of the solution, the temperature and A_s . It is not affected by the choice of the concentration units.

If $\alpha_B^A = 1$, the exchange is ideal and obeys the Law of Mass Action. However, ideal behaviour is seldom observed and preference for one of the two ions is usually shown. The rational selectivity coefficient is:

$$K_B^A = \frac{A_z^x B_s^x}{B_z^y A_s^y} \quad [7]$$

If the ions are equal valence ($x = y$) then:

$$K_B^A = \alpha_B^A \quad [8]$$

If $x \neq y$, then:

$$[\alpha_B^A]^x = K_B^A \left[\frac{A_z}{A_s} \right]^{x-y} \quad [9]$$

The corrected selectivity coefficient $K_B'^A$ includes a correction for the activity coefficient of the ions in the equilibrium:

$$K_B'^A = \frac{A_z^x B_s^x \gamma_B^x}{B_z^y A_s^y \gamma_A^y} \quad [10]$$

where γ_A and γ_B are mean ionic activity coefficients of the ions in solution.

Ion Exchange by Zeolites

The cation exchange properties of zeolites were observed some one hundred years ago. It was this property and the ease with which it was happening that led to an early interest in ion exchange materials for use as water-softening agents. The cation exchange behaviour of zeolites depends upon the following:

- Si/Al ratio;
- nature of the cation species, cation size (both anhydrous and hydrated) and cation charge;
- temperature;
- concentration of the cation species in solution;
- anion species associated with the cation in solution;
- solvent (most of the exchange is carried out in aqueous solution although some work has been done in organic solvents); and the
- structural characteristic of the particular zeolite.

The cations that contribute towards the hardness of water are calcium and magnesium ions. It is therefore evident that the property of zeolite should be such that it has a large ion exchange capacity and should be selective towards the exchange of these ions. Zeolite A, zeolite MAP, and to a certain extent zeolite X, have been shown to exhibit this property and consequently are the favourable candidates of choice towards being incorporated in the detergent formulation.

Ion exchange in zeolite A seems to be possible only with univalent and divalent counterions. Exchange of higher valence ions fails with zeolite A. The order of decreasing selectivity for univalent ions in zeolite A is as follows: $\text{Ag} > \text{Ti} > \text{Na} > \text{K} > \text{NH}_4 > \text{Rb} > \text{Li} > \text{Cs}$. For divalent ions, the order of decreasing selectivity is: $\text{Zn} > \text{Sr} > \text{Ba} > \text{Ca} > \text{Co} > \text{Ni} > \text{Cd} > \text{Hg} > \text{Mg}$.

The ion exchange kinetics depends on the zeolite structure and cation properties. As zeolite A has

Figure 6 Kielland plots for zeolite MAP and zeolite A calcium-sodium exchange, 25°C, 0.1 mol L⁻¹ solution.

a small pore diameter of 4.1 Å, the exchange of ions like Mg²⁺ is slow due to its high hydration at low temperatures. At higher temperatures, the hydration shell is reduced, making the effective ion size smaller. Thus the diffusion kinetics and in effect, exchange kinetics of Mg²⁺, are enhanced at higher temperature. Ions like Ca²⁺ diffuse easily at room temperatures as they exhibit smaller hydration. This sieving action is responsible for the selectivity of zeolite A towards Ca²⁺ ions as compared to Mg²⁺ ions.

Zeolite MAP is more selective than zeolite A towards calcium exchange. The plot of calcium selectivity constant log *K* versus the calcium loading (Kielland plot, **Figure 6**) shows peculiar behaviour for zeolite MAP. For zeolite A, as expected, the selectivity constant decreases with increase in calcium loading. In case of zeolite MAP, the opposite behaviour is observed, which indicates a cooperative exchange process. The insertion of some calcium ions in the structure causes a structural change in zeolite MAP, predisposing the framework to accept further calcium ions more readily. Its flexible structure, which was explained earlier, allows this phenomenon.

The ultimate base exchange capacity of a zeolite depends on the Si/Al ratio; it increases as the Si/Al ratio approaches unity (**Table 2**). This is the primary

reason for the dominance of zeolite A among other zeolites as far as builder applications are concerned. The table indicates that the exchange capacity of zeolite MAP approaches that of zeolite A as the Si/Al ratio approaches unity. The exchange kinetics and total exchange capacity are also dependent on the Si/Al ratio. **Table 2** shows comparison of time required to reduce concentration of 2 mmol L⁻¹ Ca²⁺ ions in a solution to the level specified. Although zeolite MAP with a Si/Al ratio approaching unity shows high capacity and faster kinetics, it becomes increasingly difficult to prepare an aluminosilicate material with a zeolite MAP structure at lower Si/Al ratios. In many cases the measured exchange capacities deviate from theoretical values due to impurities or variation in chemical composition. The specific exchange capacity also varies with the exchange cation.

Environmental Aspects of Detergent Building

STPP is a very efficient and cost-effective builder. As it is water soluble, and the hardness removal is by chelation, the process is very fast even at low temperatures. Irrespective of these advantages, many countries have stopped using STPP in detergents as it causes environmental problems. Phosphates, being essential nutrients, cause excessive fertilization in stagnant waters and slow-flowing rivers, which leads to excessive growth of algae. These problems can be avoided by employing a wastewater treatment system that removes the phosphorus. However, as aluminosilicates made an entry, it was preferred to limit the use of phosphorus compounds in detergents. Aluminosilicates are environment friendly materials. Aluminosilicates are produced by combining silica and alumina (from bauxite ore). After use in detergents, they are returned to the environment, where they decompose back to silica and alumina. The only concern about the aluminosilicates arises from their insoluble nature. There are some reports of zeolites leading to enhanced sludge in the wastewater. As long as the particles are larger than 1 µm, they can be

Table 2 Ion exchange capacity and rate of removal of Ca²⁺ from aqueous solutions by zeolites

easily removed by sedimentation. The δ -disilicate, though insoluble during the wash process, dissolves when the solution becomes dilute during the rinse cycle.

Future Trends

The builder development for detergents is now more and more driven by environmental issues. Zeolite A was a major breakthrough over the conventional phosphates. An ideal builder would be one combining the efficacy of STPP and the environment friendly nature of (alumino) silicates. At this point, combination of builders and co-builders is the way detergents are being formulated. The new materials zeolite MAP and δ -disilicate, are the future; though more efficient, they still have to cross the cost barrier to become major players in the detergent industry. As efforts are constantly underway to come up with more and more

efficient builder and detergent formulations, the challenge is to achieve compatibility, environment friendliness, and low production cost, all at the same time.

DRUGS AND METABOLITES

Liquid Chromatography–Mass Spectrometry

R. P. W. Scott, Avon, CT, USA

Copyright © 2000 Academic Press

The tandem analytical instrument, comprising a liquid chromatograph and a mass spectrometer is ideally suited for identifying drug metabolites and for following their metabolic pathways. The segregation of each drug metabolite from the sample matrix, and its subsequent identification, firstly requires a very efficient separation technique. As the metabolites are often chemically very similar to the parent drug, this exigency is adroitly furnished by the liquid chromatography (LC) column (usually microbore) packed with very small particles. Secondly, the materials of interest are inevitably present in the biological system in very small quantities and thus, despite the use of sample concentrating techniques, a very sensitive detection technique is essential. The required

high sensitivity is effectively supplied by the ion multiplier of the mass spectrometer sensor. Thirdly, in order to identify the individual metabolites, structural information is required which must be highly specific and contain adequate detail at high resolution. Such data is readily provided by the mass spectrum of each eluted solute, which can either be compared with standard spectra or identified by using well-established interpretation procedures. In some cases, the liquid chromatograph can be coupled to a MS/MS instrument that will provide mass spectra of each fragment ion, from each eluted solute, should more detailed information be needed.

For the effective use of LC/MS, special sample preparation techniques are necessary and suitable LC/MS interfaces should be employed. Both these subjects are discussed in detail in other parts of the Encyclopedia, and it will be sufficient here to give the sample preparation details of each typical application that is discussed. In addition, the general interface systems that are used, such as thermospray, electrospray, atmospheric pressure chemical ionization devices, transport interfaces etc., are also described in

detail under LC interface devices and can be referred to when appropriate. Drug and drug metabolites find their way to many parts of the body in a variety of ways: via the alimentary canal, via the blood stream, or through the lymph system, and sometimes by direct diffusion through specific tissues. In animal tests, drug and drug metabolites can be found, extracted and assayed in many specialized tissues such as the liver, kidneys, heart muscle, brain, etc. and are usually extracted using standard procedures after homogenizing the tissue. In human tests, the drug and drug metabolites are usually measured in biological fluids, such as whole blood, blood plasma, gastric fluids, urine, saliva, etc., although occasionally samples of tissue from biopsies are also examined. In simple cases of drug monitoring, the concentration of a particular drug and its metabolites may be monitored during treatment merely to ensure that the drug level is kept at an optimum for prime response. In more complicated procedures, the drug and its metabolites may be monitored in a number of different fluids and tissues to determine not only the metabolic pathway, but also those tissues and sites where specific types of metabolism or drug breakdown occur.

The unique advantages of the various techniques and procedures used in LC/MS for monitoring drugs and their metabolites are best illustrated by means of a number of carefully selected applications. There is a wide range of LC/MS applications available for drug and drug metabolite analysis and the following have been chosen as typical examples of the use of the technique in pharmacology. Furazolidone (*N*-(5-nitro-3-furfurylidene-3-amino)-2-oxazolodinone) is a 5-nitrofuran antibiotic that is added to animal feeds to help prevent such infections as *Escherichia coli* and *Salmonella* in cattle, pigs and poultry. It follows that it would be important to know the amount of residues (if any) remaining after slaughter in any meat used for human consumption. In Europe, for example, the maximum amount of furazolidone that is tolerated is $5 \mu\text{g kg}^{-1}$ of animal foodstuff. Furazolidone is light sensitive and so operations must be carried out under artificial yellow light. An example of the measurement of furazolidone in some pharmacokinetic studies is afforded by the work of McCracken *et al.* who used thermospray ionization LC/MS for its determination. The procedure that was used is as follows. 2-g samples of liver and muscle tissue were homogenized with 40 mL of a mixture of McLlvaine buffer and methanol (7:3) and then centrifuged for 15 min. The supernatant liquid was then removed and evaporated down to 15 mL at 40°C . 25 mL of dichloromethane was then added and the mixture shaken for about 1 min. The upper aque-

ous layer was discarded and the solvent extract carefully evaporated to dryness and then dissolved in a mixture of 2 mL of dichloromethane and 6 mL of hexane. The solution was then extracted by passing it through a prepared Bond-Elut NH_2 extraction cartridge, which was then washed with 5 mL of a hexane/dichloromethane mixture (1:1) and 2 mL of a hexane/chloroform mixture (1:1). The cartridge was then extracted with 5 mL of a mixture of chloroform and methanol (7:3) and the extract evaporated to dryness. The residue was then redissolved in 100 μL of mobile phase, which consisted of 0.1 mol L^{-1} ammonium acetate/acetonitrile (3:1). The sample was injected onto a reversed phase column, 12.5 cm long and 4 mm i.d., containing RP18 stationary phase bonded to 5- μm particles. Chromatograms showing the elution of the Furazolidone by single ion monitoring are shown in Figure 1. It is seen that as a result of the use of single ion monitoring, the procedure can be made highly selective. The recovery of the drug ranged between 65 and 70%. The minimum detectable level of contamination was about $1 \mu\text{g kg}^{-1}$ of tissue, which was quite adequate to confirm that a sample did not contain the drug in excess of the tolerance level.

Another example of the use of the thermospray interface for monitoring drugs in cellular matter from animals is given in the work of Cannavan *et al.* who developed a technique for measuring levamisole in pig and sheep tissue. Levamisole L-(–)-2,3,5,6-tetrahydro-6-phenylimidazole(1,1-b)thiazole, the laevorotatory isomer of tetramisole, is an anthelmintic drug used to control gastrointestinal parasites in cattle, pigs and sheep. In a similar way to that used in the assay of furazolidone, a somewhat complicated sample preparation procedure was necessary. 3 g of the tissue sample was mixed with 2 g of anhydrous sodium sulfate, 9 mL of ethyl acetate and 0.5 mL of 50% (w/v) potassium hydroxide solution, and the mixture homogenized. The mixture was then centrifuged and 6 mL of *n*-hexane was added to 6 mL of the supernatant liquid, and then passed through a Baker Bond CN cartridge column. The column was washed with 5 mL of chloroform/*n*-hexane mixture (1:1) and air-dried. The levamisole was eluted with two 5-mL aliquots of methanol, evaporated to dryness, and the residue taken up in 200 μL of the mobile phase consisting of acetonitrile–tetrahydrofuran–triethylamine–water (350:50:2:598 v/v) containing ammonium acetate (0.1 mol L^{-1}). This solution was then used for the LC/MS analysis. 50- μL samples were placed on a Li-Chrospher 60RP-select B column (12.5 cm long, 4 mm i.d), packed with 5- μm particles. Then mass spectrometer was the Hewlett-Packard 5989A MS engine with thermospray. Single ion

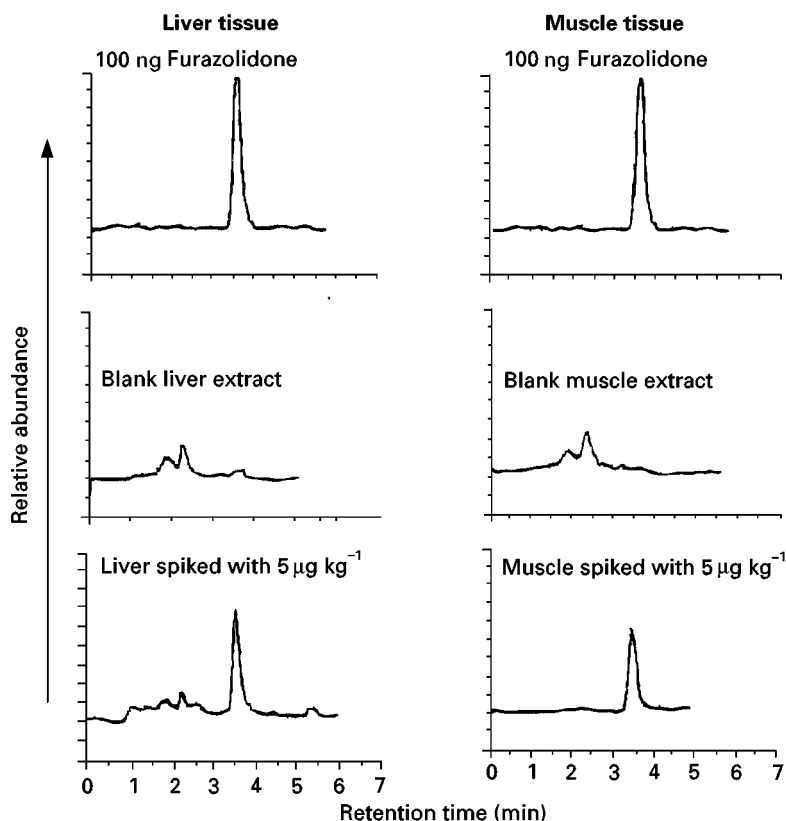

Figure 1 Single ion chromatograms ($m/z = 243$) of furazolidone demonstrating the sensitivity levels obtainable. (Reproduced with permission from McCracken *et al.*, 1995.)

chromatograms obtained from the analysis are shown in **Figure 2**. They again emphasize the advantages of single ion monitoring; the peak of interest is selected from a complex mixture of peaks with only one other appearing in the chromatogram. The limit of detection was found to be about 5 ng g^{-1} of tissue and the calculated mean recovery for liver, kidney and muscle tissue was found to be 93, 85 and 79%, respectively.

Many penicillins, particularly penicillin G, are extensively used in veterinary medicine. It follows that to prevent antibiotic residues from entering the human food chain, their levels in animal products that have been prepared for human consumption need to be carefully monitored. Blanchflower *et al.* developed a procedure for simultaneously monitoring five penicillins, including oxacillin, cloxacillin and dicloxacillin in both muscle and kidney tissue and also in milk. Blanchflower *et al.* employed an LC/MS tandem instrument fitted with an electrospray interface, and utilized single ion monitoring to selectively locate and measure each antibiotic. The extraction process was exceedingly complicated. An appropriate tissue sample was pulverized, spiked with an appropriate standard and homogenized. Acetonitrile was then ad-

ded to the homogenate, which was sonicated and finally centrifuged. A portion of the supernatant liquid was then treated with phosphoric acid mixed with dichloromethane and again centrifuged. Acetonitrile and *n*-hexane were added, the mixture shaken and again centrifuged. The lower layer was separated and then washed with water. The solvent mixture was then extracted with phosphate buffer, centrifuged once again and the lower layer treated with tetrabutylammonium hydrogen sulfate. The solution was then extracted with dichloromethane, the extract evaporated to dryness and dissolved in an acetonitrile water mixture. Separations were performed on an Intersil ODS-2 reversed-phase column (15 cm long and 4.6 mm i.d). The outlet from the column was coupled to a Megabore probe of a VG Platform ES-MS, which was operated in the negative ion mode. The source was maintained at 120°C and the flow rate of the drying and nebulizing gas was 10 L h^{-1} . The extraction and focus voltages were about 17 and 24 V, respectively. It was found that the fragmentation pattern was significantly changed by adjusting the voltage on the extraction cone. As the voltage was increased, the degree of fragmentation increased. The effect of extraction cone voltage is

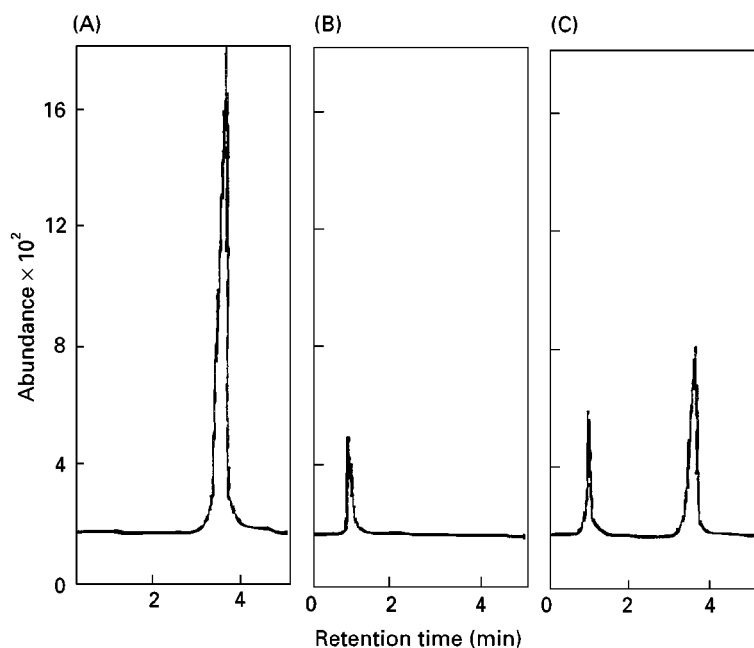

Figure 2 Single ion chromatograms of levamisole extracted from liver tissue. (A) Levamisole standard ($1 \mu\text{m mL}^{-1}$), (B) negative liver sample, and (C) liver samples + levamisole (34.8 ng g^{-1}). (Reproduced with permission from Cannavan *et al.*, 1995.)

demonstrated in Figure 3. It would appear that a potential of 5 V on the extraction cone produced just two ions above an m/z value of 160, i.e. $m/z = 434$ and 436. Increasing the potential to 10 V produced another peak at an m/z value of 293. At a potential of

Figure 3 The effect of changing the extraction voltage on the fragmentation pattern. Extraction potential 5 V (A), 10 V (B), 15 V (C) and 20 V (D). (Reproduced with permission from Blanchflower *et al.*, 1994.)

20 V, the peak at an m/z value of 293 has markedly increased and has been joined by a significant peak at $m/z = 295$. At the same time, the original major peak at $m/z = 434$ had shrunk to a minor peak and peak at $m/z = 436$ was barely visible. It is obvious that the operating conditions of the interface can be critical in order to achieve the desired selectivity and sensitivity. This effect is typical for electrospray interfaces. In the antibiotic assays, the extraction potential was maintained between 15 and 17 V. Examples of the chromatograms obtained for cloxacillin and penicillin G contained in muscle tissue and obtained by single ion monitoring at different m/z values are shown in Figure 4. It shows that monitoring at m/z values of 293, 390 and 434 selects the cloxacillin from the accompanying unresolved substances almost exclusively. It would also appear that the best signal-to-noise ratio was achieved employing m/z values of 293 and 434. The apparent magnitude of the signal-to-noise ratio indicates that the assay could detect levels of cloxacillin as low as 40 ng g^{-1} . The optimum extraction voltage for assaying penicillin G in milk appears to be far more critical, the best selectivity being obtained at a m/z value of 333. The lower limit of detection, however, is much smaller and it would appear that an antibiotic level of 1 ng g^{-1} might be detectable.

Although the technique of LC/MS is ideal for the detection and identification of drugs and their metabolites in samples of biological origin, it is often

Figure 4 Chromatogram from the assay of cloxacillin and penicillin G monitored at different m/z values. (A) Muscle spiked with 200 ng g^{-1} cloxacillin, (B) milk spiked with 4 ng g^{-1} penicillin G. (Reproduced with permission from Blanchflower *et al.*, 1994.)

necessary to use quite complicated sampling procedures. For example, Cai and Henion developed an intricate combination of sampling techniques to determine LSD and its analogues in urine. The urine sample was first subjected to affinity chromatography, which selectively removed the LSD and its metabolites from the urine. The materials isolated on the affinity column were then displaced and collected in a special trap, from which the materials of interest

were then again displaced onto the LC column for separation. The column eluent was then passed through an atmospheric pressure chemical ionization interface to the mass spectrometer. A diagram of their apparatus is shown in Figure 5. The analytical procedure was quite complicated. The immuno-affinity column that was employed was an HiPac protein G column ($3.3 \text{ mm} \times 2.1 \text{ mm}$) packed with $30\text{-}\mu\text{m}$ particles. Prior to use, the column was equilibrated

Figure 6 (A) Total ion current chromatogram of a tryptic digest sample of human growth hormone. (B) Spectrum of a product from the tryptic digest of human growth hormone obtained from low dead volume atmospheric ionization interface.

with phosphate buffered saline (PBS). 30 μL of PBS-diluted antibody solution (10% antibody/90% PBS) was then injected onto the column. Then, the sample of human urine, diluted with PBS (50% urine/50% PBS), was pumped through the protein G column and immediately flushed with PBS to remove the weakly bound impurities. While this process was taking place, the trapping column (1.5 cm long, 1 mm i.d.; packed with 5- μm C_{18} particles) and the LC column (15 cm long, 0.3 mm i.d.; packed with 3- μm C_{18} particles) were equilibrated with the mobile phase. The PBS was then pumped through the affinity column and the trap, desorbing the materials from the affinity column and re-adsorbing them on the trap. The trap was then back-flushed and the desorbed materials eluted through the LC column into an API interface and thence into the mass spectrometer. Four metabolic products in addition to the unchanged LSD itself were separated and identified from their mass spectra. The concentration of LSD in the original urine sample was 0.9 ng mL^{-1} . The results of Cai and Henion demonstrate how, by utilizing the selective extraction that is provided by affinity chromatography, very high sensitivities can be obtained.

Recently Thomson *et al.* described a modification of the atmospheric pressure chemical ionization technique involving a special low dead volume interface. Thomson *et al.* employed packed microbore columns (170, 320 and 500 μm i.d., with lengths ranging from 5 to 15 cm) in conjunction with a low-volume, wall-coated capillary column as an interface. The total ion current chromatogram of the tryptic digest sample from about 1 pmol of human growth hormone is shown in Figure 6A. The column was packed with an octadecyl bonded-phase having a mean pore size of 300 \AA and a particle diameter of 7 μm . The separation was developed by employing a gradient of from 20% solvent (0.1% TFA in water, Figure 6A) to 80% solvent (75% of 0.1% TFA and 25% acetonitrile, Figure 6B) over a period of 1 h. Flow

rates of about 80 to 100 $\mu\text{L min}^{-1}$ were used, and about 3 $\mu\text{L min}^{-1}$ of the flow was split from the mainstream and passed to the capillary column *via* the capillary interface. It can be seen from Figure 6 that an excellent separation is obtained and apparently little resolution is lost in the capillary interface. The mass spectrum of the peak marked T2 in the chromatogram is shown in Figure 6B. It is clear that good quality spectra can be obtained for ion masses of up to at least 900. Such a combination of techniques can be invaluable for the structural elucidation of compounds generated in biochemical research.

Introduction

As part of the development process of any new chemical entity as a drug substance, evidence is required that its metabolism in humans is similar to its metabolism in the animal species selected for toxicological evaluation. In order to obtain this information a number of studies are carried out using both radiolabelled and unlabelled material. Xenobiotics are generally metabolized to generate more polar compounds that are then more readily eliminated from the body. The metabolism of drugs commonly occurs in two main phases: phase I, functionalization type reactions such as oxidation, reduction and hydrolysis and phase II where metabolism reactions are generally conjugative reactions such as glucuronidation, sulfation, methylation, and acetylation whereby an endogenous group is attached to the molecule.

Historically drug metabolite identification has usually been based on the comparison of UV detected high-performance liquid chromatography (HPLC) retention times of isolated 'unknown' metabolites with authentic standards. This method of detecting drug metabolites, and subsequently characterizing, is not only a time-consuming process, and hence expensive, but yields no or very limited structural information.

The application and use of mass spectrometry in drug metabolism studies has contributed significantly to the improved structural characterization of novel drug metabolites. More recently, tandem mass spectrometry (MS/MS) has been increasingly used in both the characterization and quantitation of metabolites in microsomal incubates, urine, plasma and faecal extracts derived from both *in vitro* and *in vivo* sources.

Even though mass spectrometry is an exquisitely sensitive and specific detector capable of providing drug metabolite information from complex biological matrices, it does not always provide unequivocal structural identification, and in these instances NMR spectroscopy is often needed to provide conclusive site specific structural characterization. Increasingly the complementary information provided by MS and NMR is used in conjunction with HPLC separation techniques and indeed reports exist where all three techniques have been linked to generate on-line LC/NMR/MS.

A Systematic Approach to Drug Metabolite Identification

This section describes an approach to drug metabolite identification which utilizes semi-preparative HPLC, LC/MSⁿ, NMR and HPLC/NMR. The potential of coupling NMR and tandem mass spectrometry (MSⁿ) in the form of an ion trap mass spectrometer is also highlighted. The advantage of using an ion trap mass spectrometer over a quadrupole instrument is primarily the ability to generate MSⁿ spectra by repetitively isolating and fragmenting stored ions, and thereby producing second, third and subsequent generation product ions. This enables advantage to be taken of both structural and molecular weight information generated by the MS to complement the NMR data. The power of the use of these techniques in combination with each other is illustrated, using the example of novel non-nucleoside reverse transcriptase inhibitor, GW420867 (see **Figure 1**) which serves to demonstrate the approach currently taken to drug metabolite characterization in our laboratory.

Sample Fractionation

Urine samples collected following oral administration of GW420867 to animal species and man were pooled to provide 100 mL of sample in each case. The pooled urine samples were separately freeze-dried and then reconstituted in distilled water to give a final volume equal to one tenth of the initial volume. The resulting concentrated urine samples were centrifuged and the supernatants removed and stored at 0–8°C prior to isolation by preparative HPLC. Injections of the concentrated urine samples (10 mL) were made onto a preparative HPLC column, and analytes separated with reversed-phase gradient elution. The column eluent was collected into 96 well microtitre plates at 15 s fraction intervals. The microtitre plates were transferred to a 96 well dry down station

Figure 1 Structure of GW420867.

Figure 2 ^1H -NMR spectrum of a 1 mg mL^{-1} solution of authentic GW420867X in 50:50 acetonitrile – deuterium oxide, obtained on a Bruker DRX-600 spectrometer over 256 scans with dual solvent suppression.

and evaporated to dryness under a constant flow of nitrogen at 25°C . The dried fractions were re-dissolved in 50:50 acetonitrile – deuterium oxide. The microtitre plates were sonicated for 10 min in an ultrasonic bath to aid the resolution process and the resulting dissolved fractions transferred individually to 5 mm NMR tubes for analysis by ^1H and ^{19}F NMR spectroscopy for the presence of drug-related material.

Fraction Screening by ^1H and ^{19}F NMR

In this particular example the ^{19}F NMR spectra may be used to ascertain the distribution of drug-related material in the processed fractions as the drug

molecule contained a fluorine atom and there are little or no endogenous fluorinated background signals in urine. However comparison of the ^1H NMR spectra obtained for the isolated fractions with that acquired for the authentic parent compound may also be used for this purpose. The ^1H NMR spectrum of the parent drug is shown in **Figure 2**. The aromatic protons at 6.78 and 6.94 ppm and the aliphatic protons at 0.85 and 1.29 ppm were used to identify possible drug metabolites and also to indicate structural changes where appropriate. By contrast the ^{19}F NMR spectra only provides limited structural information on changes in the immediate vicinity of the fluorine atom.

Figure 3 ^1H -NMR spectrum of the H-5 hydroxyl glucuronide metabolite of GW420867X in-acetonitrile – deuterium oxide (1:1) obtained on a Bruker DRX-600 spectrometer over 64 scans with dual solvent suppression, following isolation from rabbit urine.

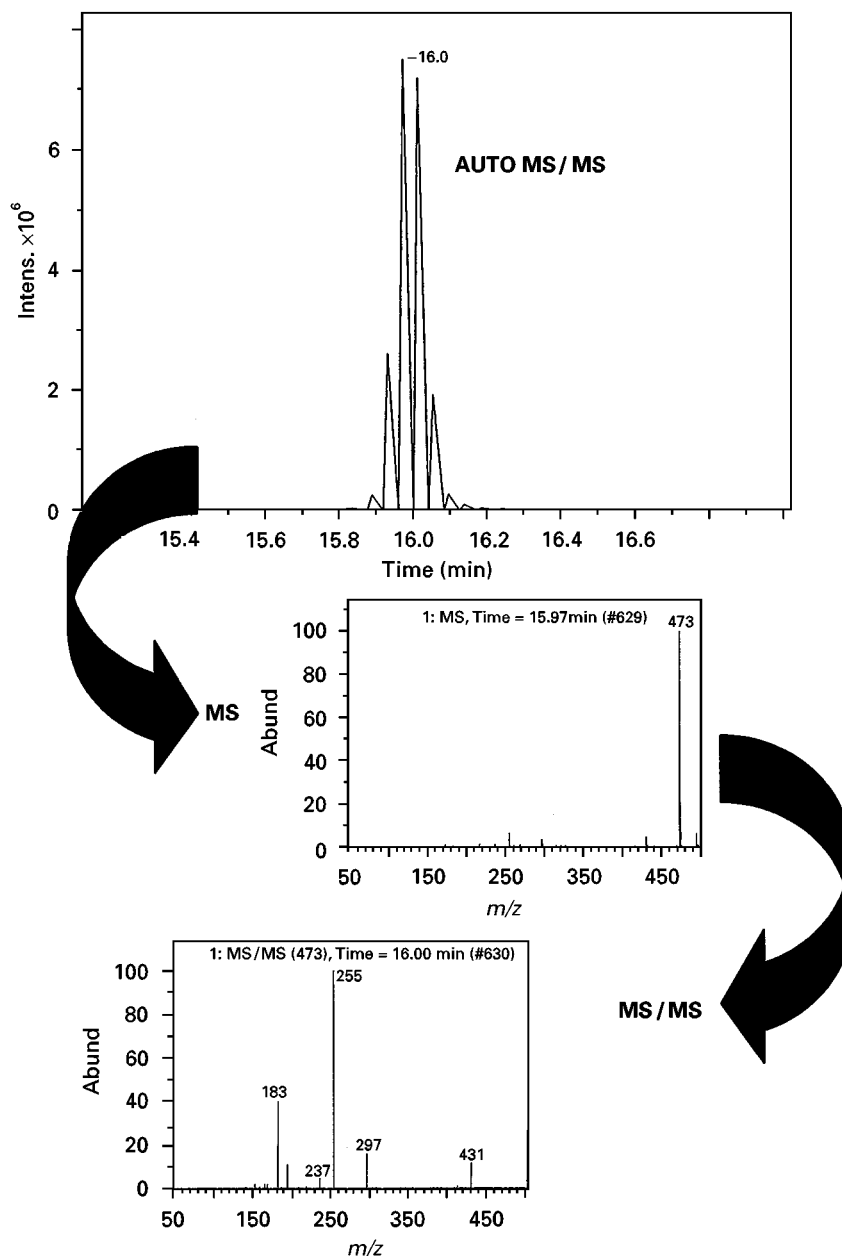

Figure 4 LC/MS/MS analysis of the H-5 hydroxyl glucuronide metabolite of GW420867X following injection of a rabbit urine fraction on to a 250×4.6 mm Zorbax RX-C8 $5 \mu\text{m}$ column. Analytes were eluted with a 0–100% aqueous 0.1% formic acid/acetonitrile gradient over 30 min at 1 mL min^{-1} . The column eluent was monitored using the Esquire ion trap operating in positive ion electrospray ‘auto’ MS/MS, with a resonance fragmentation amplitude of 1.2 V.

A ^1H NMR spectrum from an isolated rabbit urine fraction acquired using only 64 scans, is given in Figure 3 and illustrates that metabolites can potentially be isolated with high degree of purity. Inspection of the ^1H NMR spectrum readily enabled the metabolite to be identified as a glucuronic acid conjugate of the 5-hydroxylated species (as shown in Figure 3); the anomeric H1 (5.1 ppm) and H2–H5 (3.4–3.6 ppm) glucuronyl protons being clearly visible.

Analysis of Metabolite Containing Fraction by Mass Spectrometry

Fractions highlighted using ^{19}F and ^1H NMR spectroscopy as containing drug-related material were further investigated using electrospray LC/MS/MS operating in data dependent MS/MS mode. Small injections enabled discernible MH^+ or $[\text{M} - \text{H}]^-$ ions for all metabolites to be obtained to provide complemen-

Figure 5 Rationalization of the product ions resulting from MS/MS of the isolated H-5 hydroxyl glucuronide of GW420867.

tary molecular weight and structural information to supplement. LC/MS/MS chromatograms and spectra corresponding to the NMR spectrum in Figure 3 are given in Figure 4. This metabolite could be rationalized as a hydroxyl glucuronide (see Figure 5), and therefore complemented the NMR data already acquired. In common with many glucuronide conjugates, the loss of the glucuronyl moiety in the MS/MS spectrum (-176 amu) is clearly observed. MS/MS data interpretation of all spectra was assisted by comparison with the MS/MS spectrum of an authentic standard.

The example cited above is an extremely common and representative example where the precise position of aromatic protons are established unequivocally through the use of ^1H NMR spectroscopy. The MS data provided added confidence by providing both molecular weight and some structural information. Thus by combining the NMR and MS data full structural elucidation is more effectively and rapidly achieved. Thus for GW4208657 using NMR and MS as described above, a total of 17 metabolites were unequivocally identified following extraction from various matrices.

Figure 6 The LC/NMR/MSⁿ system was configured as depicted by connecting the Bruker DRX-600 NMR spectrometer and the Bruker–Esquire mass spectrometer in series. In this configuration the mass spectrometer was operated just outside the 5 Gauss line of the NMR magnet.

Further Analysis Using Directly Coupled LC/NMR/MSⁿ

In most cases metabolites isolated directly from the preparative HPLC fractions alone gave satisfactory ¹H NMR and MS spectra and could therefore be readily characterized without further investigation. However some fractions which had either a low concentration of metabolite or which were

impure mixtures of metabolites required further separation and/or longer data acquisition using LC/NMR/MSⁿ.

LC/NMR probes are generally more sensitive than standard NMR probes as the sample is concentrated into a smaller volume by the chromatographic process and the superior filling factors (this is the proximity of the NMR RF coils to the sample) obtained in LC/NMR probes.

Figure 7 Chromatogram, mass spectrum and ¹H NMR spectrum acquired following the injection of a human urine fraction onto the LC/NMR/MSⁿ system illustrated in Figure 6. The peak at 13.3 min was trapped in the NMR flow probe, and a ¹H NMR spectrum acquired over 256 scans. The peak was then pumped into the ion trap through the electrospray source and the subsequent mass spectrum acquired in positive ion mode using deuterated solvents. Chromatography was performed on a 250 × 3.2 mm Phenomenex Magellen C18 column, eluted with a 0–80% aqueous 0.1% formic acid/acetonitrile gradient, over 35 min.

Additionally the combination of LC/NMR/MS allows an impure fraction to become further purified through the use of an analytical chromatographic system step following the initial semipreparative isolation. An example of the use of LC/NMR/MS for the identification of a novel human urine metabolite of GW420867 is given below.

For the application of LC/NMR/MS the instruments are configured in series as shown in Figure 6. This arrangement allows easy operation of peak storage followed by transfer to the NMR spectrometer and stop flow analysis, and it avoids difficulties with synchronization of the NMR and MS data capture; NMR data acquisition occurs first.

Following acquisition of the ¹H-NMR spectrum, the metabolite was transferred from the NMR probe to the ion trap mass spectrometer, where MS and MSⁿ spectra were obtained. The system was operated in one of two ways; in one approach, the flow from the NMR probe was split directly into the electrospray interface. In this mode, the presence of deuterium oxide in the mobile phase produced MD⁺ ions in which all labile hydrogens had been exchanged with deuterium. In the second mode, an aqueous make up flow was employed to effect

deuterium ‘back exchange’, resulting in undeuterated MH⁺ ions.

An UV chromatogram acquired from an on-line LC/NMR/MSⁿ analytical run from a human urine fraction is shown in Figure 7 and indicates the presence of three main peaks. The ¹H NMR spectrum and the resulting MS spectrum acquired for peak III, eluting at 13.3 min is also shown in Figure 7. Inspection of the ¹H NMR spectrum indicates that aromatic substitution has occurred in the position meta to the fluorine-bearing carbon, resulting in the loss of an aromatic proton. The remaining 2 aromatic protons at 6.84 ppm (doublet of doublets, *J* = 10.6 Hz and 1.47 Hz) and 7.15 ppm (broad due to restricted rotation at the amide bond) are consistent with substitution in the 5-hydroxy position.

The presence of glucuronic acid anomeric H1 proton at 5.04 ppm suggests the presence of a glucuronide. Calculation of the signal integrals in the aliphatic region at 1.26 ppm indicated the loss of one of the isopropyl methyl groups. Hydroxylation at the isopropyl group would generate a CH₂OH group whose protons will be evident in the NMR spectrum in the region of 3.5 ppm. Although these signals could not be clearly observed, as the signals from the H2–H4 of

the glucuronic acid were obscuring this region, the sum total of integral values of all the protons in this region indicated the presence of five protons. This was in support of the hypothesis of hydroxylation at the isopropyl methyl.

The MS spectrum shown in Figure 7 was acquired by directly coupling the LC/NMR probe outlet to the MS. As NMR spectra are acquired in a mixture of D₂O/ACN the resulting ion at m/z 496 from this directly coupled arrangement is in a deuterated form (MD^+). In order to simplify matters an MS spectrum of the same peak was acquired, using the 'back exchange' configuration, which allows all the deuterium atoms to be exchanged with hydrogens. This is given in Figure 8. In this spectrum the MH^+ ion can be observed at m/z 489, which indicates that there are six exchangeable hydrogens on the original metabolite. Subsequent MS^4 experiments on m/z 489 were conducted as the peak eluted into the ion trap and these MS/MS spectra are also given in Figure 8. MS^n spectra enhance the interpretation of the original MS/MS spectrum and can be used to assist the elu-

cination of the structure and fragmentation pathway, as shown in the case of this novel human urinary metabolite. In this example, comparison of the product ions at m/z 183 and 255 to their equivalents formed from parent drug (m/z 167 and 239 respectively, data not shown), indicates aromatic hydroxylation the position of which was confirmed by the 1H NMR spectrum. Loss of the isopropyl group to generate m/z 255 from m/z 313 suggested that the site of secondary hydroxylation was the isopropyl group, and this is supported by the NMR data. The use of an ion trap mass spectrometer providing molecular weight and structural fragmentation information, from MS and MS^n experiments respectively, when combined with NMR provides an extremely powerful structure elucidation tool.

Conclusions

The importance of combining data from different analytical techniques has been demonstrated. NMR and MS^n have been coupled with preparative and

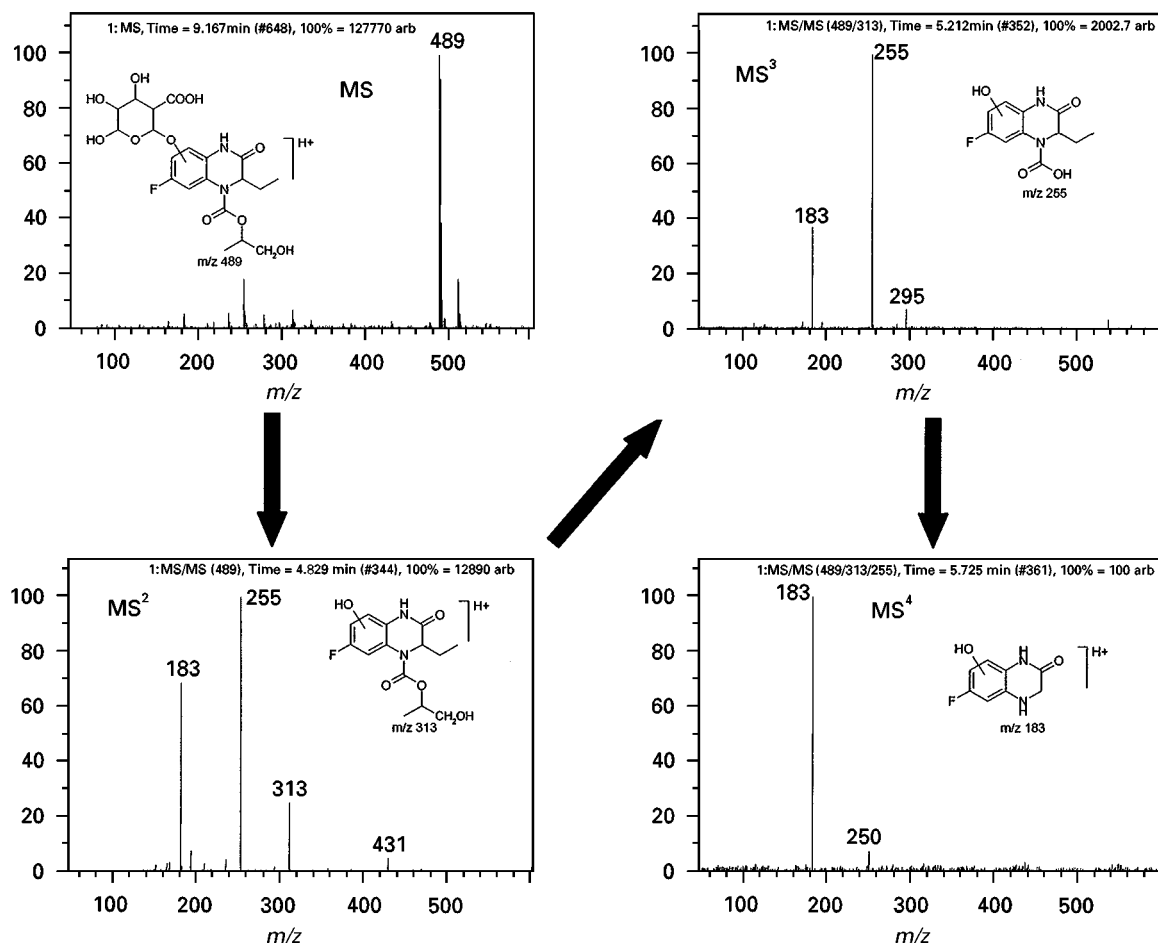

Figure 8 MS and MS^n spectra acquired following the injection of human urine fraction onto the LC/NMR/ MS^n system operating in 'back-exchange' mode. Fragmentation was induced using a resonant excitation amplitude of 1.2 V, following mass isolation.

analytical HPLC to allow rapid and effective identification of metabolites in urine, following the oral administration of GW420867. The combination of these techniques enables structural and molecular weight information to be interpreted with greater efficiency and accuracy.

Future Prospects

The advantages of capillary HPLC and nanospray MS, both 'miniaturized' versions of their predecessors, HPLC and electrospray, are well documented and there is also a move towards miniaturization in most other modern analytical techniques. The enhanced sensitivity obtained by capillary LC using a capillary UV flow cell may be extended to NMR, with the development of capillary NMR flow cells. The higher efficiency separations and reduced band broadening that result from capillary LC has the effect of producing a more concentrated sample eluting from the column and therefore a higher sample concentration into the NMR flow cell. This potentially leads to a better signal to noise ratio at lower analyte concentrations in the acquisition of NMR data. A further advantage of capillary LC is the reduced solvent consumption associated with this

technique, which can lead to particularly significant cost-savings when dealing with the expensive deuterated solvents used in NMR spectroscopy. Residual protonated solvent suppression in the NMR spectrum then becomes an easier task.

Capillary LC and capillary electrochromatography (CEC) coupled to mass spectrometry are already in widespread use within the pharmaceutical industry and therefore the connection of capillary LC or CEC to both NMR and MS would be a natural progression.

DRUGS OF ABUSE: SOLID-PHASE EXTRACTION

F. Musshoff, Institute of Legal Medicine, Bonn, Germany

Copyright © 2000 Academic Press

Introduction

In toxicological analysis, two basic approaches can be distinguished: first, a directed search, geared to a limited number of substances, such as in workplace testing or the analysis of alcohol or special drugs in traffic offences; and second, an undirected search, also called systematic toxicological analysis (STA). STA can be defined as an undirected search for potentially harmful substances whose presence are uncertain and whose identities are unknown. STA is required if little or no information is available in so-called general unknown cases. However, if one toxicant is known, the analyst is required to establish whether other compounds of toxicological relevance are present.

The drug screening process can generally be divided into two stages, sample preparation and analysis of the drugs. Some forms of sample work-up – isolation and concentration – are required for most analytical techniques, such as thin-layer chromatography (TLC), high performance liquid chromatography (HPLC) and gas chromatography (GC) coupled to various detector systems. The samples available for analysis are complex biological matrices, in which toxicologically relevant substances are present in trace amounts compared to the endogenous compounds present. Therefore, work-up procedures should retain all relevant substances, at the same time removing all irrelevant substances and interferences.

Liquid-liquid extraction (LLE), often combined with sample pretreatment procedures such as conjugate hydrolysis, digestion or protein removal, was the standard method in the past. Although LLE proved to be suitable in a great number of cases, there are many disadvantages of this technique, e.g. matrix interferences, emulsion formation or the use of large

volumes of organic solvents. In recent years, sample preparation by solid-phase extraction (SPE) has received widespread interest and today many types of SPE materials are commercially available (Table 1). Most publications have been geared towards the isolation of one compound or a limited number of substances, i.e. directed analysis. However, in STA (undirected analysis), a compromise between acceptable recovery of many substances and adequate removal of matrix compounds should be reached. In order to develop a SPE method, each step of the procedure should be evaluated very carefully, including the selection of a suitable sorbent, the pH of the sample and the extraction system, the clean-up step, the properties and the volume of the eluent, the flow rate of the sample and the eluent passed through column.

Pretreatment of Biological Fluids and Tissues

The main purposes of sample pretreatment are first, release of drugs from the biological matrix; second, removal of proteins and other compounds which could interfere with further analysis; and third, adjustment of the pH, ionic strength and concentration of the sample to allow optimum extraction.

For the analysis of plasma/serum samples, buffer solutions are widely used for dilution. Protein precipitation is a common method to obtain deproteinized samples. Proteins can be precipitated by organic solvents, inorganic salts, metallic ions or acids (Table 2). However, it must be emphasized that co-precipitation often results in losses of the relevant drugs. Urine

Table 2 Relative efficiencies of various protein precipitants towards removing proteins

Precipitant	pH of supernatant	Volume of precipitant (mL) to precipitate > 98% protein in 0.5 mL plasma
Trichloroacetic acid, 10% (w/v)	1.4–2.0	0.2
Perchloric acid, 6% (w/v)	< 1.5	0.4
Tungstic acid	2.2–3.9	0.6
Metaphosphoric acid, 5%	1.6–2.7	0.6
Copper sulfate–sodium tungstate	5.7–7.3	1.5
Zinc sulfate–sodium hydroxide	6.5–7.5	2.0
Zinc sulfate–barium hydroxide	6.6–8.3	2.0
Ammonium sulfate (saturated)	7.0–7.7	2.0
Acetonitrile	8.5–9.5	1.5
Acetone	9.0–10.0	1.5
Ethanol	9.0–10.0	2.0
Methanol	8.5–9.5	2.0

samples can usually be diluted like plasma/serum samples. However, since many relevant substances or metabolites will be excreted in a conjugated form, a deconjugation step prior to SPE is recommended. Because of the highly variable salt content, the urine samples should be diluted with at least an equal volume of water or buffer before applying the sample on to the SPE column. This is particularly important when ion exchange is the preferred extraction mode; otherwise counterions may compete with the relevant drugs during sample application and result in losses of the latter. Sonication combined with buffer dilution is a useful technique for the pretreatment of whole blood samples. For pretreating tissue samples, homogenization followed by enzyme digestion (i.e. papain, subtilisin-A, neutrase, collagenase or trypsin) and/or protein precipitation and centrifugation of samples such as liver, kidney or intestine prior to application on to SPE cartridges are useful. Brain tissue with a high content of lipids can be used after incubation with lipase prior to extraction. High flow SPE columns are available for use with more viscous fluids.

As in LLE, pH is an important factor in SPE. The optimal pH values of the sample and the extraction system depend on the properties of the relevant drugs and the sorbent and the interaction between the drugs and the functional groups of the sorbent. When a nonpolar sorbent, for example, octadecyl-bonded silica (C_{18}), is used, the main interactions are van der Waals forces/hydrogen bonding. Therefore, the pH of both sample and the column should be adjusted to a value so that the relevant drugs are in their uncharged forms. With ion exchange as the underlying principle, the pH of the sample must be adjusted to such a value that most of the drugs are charged, so that they can be retained on the column by the opposite charge of the functional groups of the sorbent. Additionally, total ionic strength of the sample is important in ion exchange SPE. A low ionic strength, often obtained by diluting the sample with water or a low ionic strength buffer solution ($< 0.1 \text{ mol L}^{-1}$) is preferred, because any species that can act as counterions reduces the retention of ionic drugs.

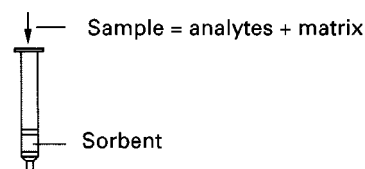

The Principles of Solid-phase Extraction

SPE is a physical extraction process that involves a solid phase and a liquid phase. It is based on the principle of liquid chromatography, but with different purposes. The aims of SPE are to isolate the relevant compounds from a sample matrix and to concentrate them, while those of liquid chromatogra-

1. Condition column with appropriate solvent

2. Apply sample on to column

3. Aspirate/force sample through column

4. Remove impurities with wash solvent

5. Elute analytes with elution solvent

Figure 1 Solid-phase extraction process.

phy are to separate each compound with a good peak shape and with relatively short retention times. Today, various sorbent materials are commercially available. **Figure 1** illustrates the steps of SPE. The column is first conditioned with an appropriate solvent to solvate the functional groups of the sorbent. After the solvent is further conditioned with the sample matrix buffer, the pretreated sample is forced

through the sorbent by aspiration or positive pressure. The column containing retained analytes is subsequently washed with an appropriate solvent that selectively elutes the impurities but leaves the analytes on the column. The purified analytes are finally eluted with a solvent strong enough to displace the analytes from the sorbent.

Basic Types of Solid Phases

Diatomaceous Earth (Extrelut®, Chemelut®)

The principle of SPE using diatomaceous earth is closely related to conventional LLE. The aqueous phase is absorbed on to the diatomaceous earth, a porous material which acts as support for the aqueous phase. This provides a large surface area for partition into an elution solvent, which flows through the immobilized specimen on the column under gravity. The elution is a continuous process and may give superior recoveries in a shorter time compared to LLE. Other advantages are the elimination of centrifugation, aspiration and filtration steps and the prevention of emulsion formation. However, relatively large volumes of organic solvents are still required. For screening purposes this type of SPE must be carried out with at least two columns: one for acidic and neutral substances and one for basic and neutral compounds. A typical procedure with this type of material is as follows: the biological sample is diluted with an appropriate buffer and poured on to the column. The bed mass of the column and the sample volume must be in agreement with each other. After a 10–15 min equilibration period, twice the volume of the diluted aqueous sample is used for elution from an organic solvent, which is waterimmiscible.

Styrene-divinylbenzene Resin (SDB)

Polystyrene-divinylbenzene copolymer (e.g. XAD-2) is a hydrophobic resin that can absorb many water-soluble organic compounds, principally by van der Waals forces and additionally by hydrophobic bonding and dipole–dipole interactions. For binding to the resin the substances must be in a hydrophobic state. Therefore, usually two columns are needed: one for acidic and neutral substances and one for basic and neutral compounds. Generally the extracts are clean enough to allow GC or TLC determinations at therapeutic and toxic concentrations. SDB resin is especially interesting for analysing urine samples since glucuronide and sulfate conjugates can be isolated. However, the extraction yields of drugs isolated from different biological samples may vary considerably. The resin has to be

cleaned very carefully, otherwise interfering substances originating from the resin will appear in the extracts. SDB extractions in columns have now been largely replaced by SPE using silica-based columns. Recently, new SDB-based SPE columns (e.g. Bond Elut ENV, Varian) have become available, with which the drawbacks may be overcome. A typical procedure with this type of material is as follows: the biological sample is diluted and the pH is adjusted to the desired value. The resin is washed with four column volumes of acetone, three column volumes of methanol and three times with three column volumes of distilled water. The diluted sample is passed through the column where the analytes are absorbed. After the resin is washed with water, the analytes are eluted with an organic solvent (e.g. methanol, ethyl acetate, methanol–chloroform, acetone–diethyl ether, etc.).

Octadecyl-bonded Silica

Octadecyl-bonded silica absorption phases (e.g. C₁₈-end-capped) are often used for the directed search to a limited number of substances, such as in testing for special drugs of abuse in traffic incidents. The nonpolar phase retains, at a suitable pH, substances by hydrophobic interactions with the alkyl chains. For example, the simultaneous analysis of tetrahydrocannabinol (THC) and its metabolites, 11-hydroxy-THC (11-OH-THC) and 11-nor- Δ^9 -THC carboxylic acid (THC-COOH) in serum samples is possible as follows: the biological sample is diluted with 0.01 mol L⁻¹ acetic acid and the pH is adjusted to 4. An organic solvent (methanol) is used to solvate the bonded functional groups and to remove organic residues from the sorbent. Buffer is added afterwards to exchange the organic solvent with an aqueous solution. The diluted sample is passed through the column where analytes absorb. After the column is washed with water followed by a solution of 40% acetonitrile in water, the analytes are eluted with acetonitrile (Figure 2).

Mixed-mode Bonded Silica

The most widely used SPE materials are bonded silica gels, in which end silanol groups have been derivatized with organic moieties consisting of alkyl chains with and without a variety of functional groups, such as –OH, –C₆H₅, –NH₂, –CN, –SO₃H and –COOH. Based on the modes of the interaction mechanisms between the functional groups of the SPE materials and the relevant compounds, the extraction can be divided into three types: nonpolar, polar and ion exchange. However, there is no bonded silica SPE column which only contains one type of functional

Figure 2 GC-MS chromatogram recorded in the selected ion monitoring (SIM) mode. The serum sample was worked up using a C_{18} -end-capped extraction column and after derivatization of the dried extract using MSTFA after cannabinoids had been determined: THC (5.2 ng mL^{-1}), 11-hydroxy-THC (4.5 ng mL^{-1}) and THC-COOH (105.6 ng mL^{-1}).

group. Multiple modes of interactions will happen during the extraction process and the influence of secondary interactions should be kept in mind. Additionally, in so-called mixed-mode silica-bonded SPE columns, the silanol groups are partially derivatized with medium length alkyl chains and partially with cation exchange substituents, which can exert at least two types of interactions. Screening procedures using this type of SPE material have been of increasing interest and SPE columns with mixed-mode phases are available from a number of manufacturers, e.g. Bond Elut Certify (Varian Sample Preparation Products), Clean Screen DAU (Worldwide Monitoring Corp.), Isolute HCX (International Sorbent Technology) and TSC (Merck). Mixed-mode bonded silica can retain, at a suitable pH, acidic and neutral substances by hydrophobic interactions with the alkyl chains and the basic substances by interactions with the cation exchange groups. Differential elution can take place by a suitable adjustment of the pH and the choice of solvents.

A typical extraction procedure is described here in more detail.

Sample pretreatment Dilution with a 0.1 mol L^{-1} phosphate buffer at pH 6.0 is most widely used. At this pH the weakly basic, the neutral and the weakly acidic compounds, such as barbiturates, are in the nonionized form and retained by the octadecyl substituent of the sorbent. However, strongly acidic compounds like many nonsteroidal anti-inflammatory drugs are deprotonated, ionized and therefore not retained. When blood samples are brought to lower pH values coagulation of proteins occurs, resulting in difficulties in the sample applica-

tion step. When a serum or plasma sample is added to 0.1 mol L^{-1} phosphoric acid, this coagulation can be avoided.

Column preconditioning The dried sorbents in SPE columns are not in a state to interact with analytes and appropriate conditioning is required prior to sample application. For nonpolar and multiple-interaction phases (mixed-mode), the sorbent must be preconditioned with suitable solvents, for example methanol, followed by water or a buffer wash. The organic solvent used is to solvate the bonded functional groups and to remove organic residues from the sorbent. Water or buffer, of which the pH, ionic strength and polarity have been adjusted, is added afterwards to remove the organic solvent with an aqueous solution to prepare the SPE column to receive an aqueous sample. For a polar phase, for example aminopropylsiloxane-bonded silica, the column needs to be treated with a nonpolar solvent, such as hexane, to activate the surface.

Sample application After column preconditioning, the pretreated sample is transferred onto the SPE column and is drawn through it by applying a light vacuum. Normally the flow rate of sample passing through the SPE cartridge should be kept to $1\text{--}2 \text{ mL min}^{-1}$.

Column wash and pH adjustment Usually the column is washed with $1\text{--}2 \text{ mL}$ deionized water or an appropriate solvent (20% methanol in water) selectively to remove the impurities which may interfere with the analysis. To find a wash solvent which is

able to clean the column effectively without losses of the drugs, the analyst must compromise between acceptable recoveries of a great number of different substances and adequate removal of matrix compounds. In many cases, pH adjustment is introduced into this stage to bring the pH of the column to a given value for selective, pH-dependent elution of the drugs. In order to get a reproducible differential elution using mixed-mode bonded silica, the pH of the column has to be adjusted to about pH 3. At higher pH values a large number of basic compounds will elute in the first fraction (acidic and neutral substances). Lower pH values can cause deterioration of the extraction column. To adjust pH, 0.5–1.0 mL diluted acetic acid is sufficient.

Column drying Drying of the columns is necessary when no water is allowed in the analysing step (GC). Drying is carried out by applying vacuum to the column for about 5 min or centrifugation of the column. Further drying can be carried out by applying a small volume of methanol (50 μ L) or a larger volume of hexane (1 mL) followed by vacuum. A dry column is easily obtained, but there is a risk of partially eluting hydrophobic substances such as benzodiazepines in this wash process.

Elution of relevant drugs For drug elution, the eluent should be strong enough so that the drugs can be eluted completely with a reasonably small eluent vol-

ume. Furthermore, the eluent should be selective, so that interfering compounds will not be eluted together with the relevant drugs. Theoretically, eluent selection may be achieved by considering the polarity index (P'), the solvent selectivity and the eluotropic strength (ε^0) of the solution solvents. The strength of a solvent is its ability preferentially to dissolve compounds according to polarity, while the selectivity is its ability selectively to dissolve one compound as opposed to another. Solvents have been classified into eight selectivity groups according to their proton donor, proton acceptor and dipole interaction characteristics. Figure 3 represents the properties of various solvent groups with different selectivities. For example, solvents in group I are strong proton acceptors/weak donors with intermediate dipole moments and solvents in group VIII are relatively strong donors/weak proton acceptors with virtually no dipole interactions.

The P' values and the selectivities of common solvents used in SPE are listed in Table 3. The desired P' value can be obtained by using a binary mixture and can be calculated by the following equation:

$$P' = \phi_a P_a + \phi_b P_b \quad [1]$$

where ϕ_a and ϕ_b are the volume fractions of solvents A and B in the mixture; P_a and P_b are the P' values of the pure solvents A and B. In practice, both P' and selectivity of the solvents should be considered when selecting the best eluent system to elute drugs but not the impurities. Data shown in Table 3 indicate that the P' values of 2-propanol, chloroform and ethyl acetate are very similar, yet they belong to different selectivity groups.

The eluotropic strength ε^0 , which defines solvent strength quantitatively for a given adsorbent, is another helpful parameter for choosing a suitable eluent. The eluotropic strength is the adsorption energy per unit area of the solvent and Table 3 lists the ε^0 values of some common solvents and binary mixtures. This knowledge can be helpful in the development of a new SPE method. If a certain eluent system gives high recoveries of test drugs but also elutes many impurities, the use of another eluent mixture with a similar ε^0 value could be helpful.

The volume of a selected eluent is another important factor in the development of an extraction procedure. Generally, the volume of the eluent should be as small as possible. Increasing volumes will prolong the extraction period, may elute more impurities and may lose more volatile drugs (such as amphetamines) when an evaporation step is required after column extraction. The flow rate of the eluent passing through the column should allow adequate interac-

Figure 3 Classification of solvent selectivities (the Roman numbers represent various groups of solvent selectivities). χ_e , χ_d and χ_n represent the fraction of P' contributed by interactions associated with ethanol (acceptor), dioxane (donor) and nitromethane (polar). tion. When ion exchange is the main interaction, the flow rate should be $<2 \text{ mL min}^{-1}$ since ion exchange interactions occur at a slower rate than polar and nonpolar interactions.

Using mixed-mode bonded silica extraction columns in the first fraction, fraction *A*, the analytes retained by the hydrophobic groups of the sorbent are eluted using a moderately polar solvent like dichloromethane or combinations, e.g. acetone–chloroform (1 : 1), hexane–diethyl ether (40 : 60), hexane–ethyl acetate (75 : 25). To avoid dirty extracts in the second fraction, fraction *B* (basic compounds), an in-between polar washing step, for instance with methanol, may be needed.

The basic substances retained by the cation exchange groups of the sorbent in their protonated form are eluted by an organic solvent mixture, usually with 2% ammonia. Ammoniated ethyl acetate or ammoniated dichloromethane–2-propanol (80 : 20) for the elution of more polar substances is widely used. Table 4 gives an overview of extraction methods using mixed-mode SPE phases for drug screening. Amphetamines and other relatively volatile substances often show lower recoveries, probably caused by evaporation in the final step of the SPE procedure. Polar drugs like acids and acetaminophenes are scarcely retained under the condition used and

may be washed away. Therefore, an additional LLE on the sample coming from the column and column wash could be introduced in a general screening procedure.

Conclusions and Further Developments

The use of SPE for the toxicological analysis of drugs of abuse in biological samples has increased rapidly. Due to the different properties of the drugs of interest, mixed-mode SPE columns are better suited for screening purposes than single-mode columns. However, although the same type of SPE material can be obtained from different manufacturers, the results using different materials, and even results obtained from different batches from the same manufacturer, may show significant differences in behaviour, i.e. in particle size distribution and flow velocities. Today, chemically modified silica and SDB sorbents are also available in extraction discs. These materials are very promising, since samples can be processed faster using smaller volumes of organic solvents while still allowing relatively large sample volumes. Furthermore, extractions can be performed outside working hours by automation of manual SPE methods with the addi-

Copyright © 2000 Academic Press

Countercurrent chromatography is one of the liquid-liquid partition chromatographic techniques that do not use a solid support. High-speed countercurrent chromatography (HSCCC) uses centrifugal force to retain one of the liquid phases in an lto multilayered coil column while the second liquid phase is pumped through the column. The principles of this technique have been discussed by Ito.

HSCCC in its two forms, conventional and pH-zone-refining CCC, is relatively new among the preparative techniques used for the separation of dyes. Conventional HSCCC has been applied to this purpose since the mid-1980s when Fales *et al.* separated various components present in a sample of the triphenylmethane biological stain, Methyl Violet 2B, and when Freeman and co-workers purified azo textile and ink dyes (i.e. acid, direct and disperse azo-dyes). This technique was subsequently used for the separation and purification of components from other colours, such as D&C Red No. 28 (Phloxine B, CI 45410), Sulforhodamine B (CI 45100) and Gardenia Yellow. It was also effectively implemented as a complement to preparative high performance liquid chromatography (HPLC) for the separation of a complex synthetic mixture of brominated tetrachlorofluorescein dyes. Conventional HSCCC was applied to the separation of quantities of dyes of up to several hundred milligrams when the common 1.6 mm i.d./325 mL volume column was used. By contrast, the more recently developed (1993) pH-zone-refining

CCC was applied from the outset to the separation of multi-gram quantities of dye mixtures such as xanthene and fluoran dyes used as colour additives in food, drugs or cosmetics and as biological stains.

Using a modified procedure, the applications of this technique have been extended to the separation of gram quantities of the highly polar mono-, di- and trisulfonated components of D&C Yellow No. 10 and Yellow No. 203 (both Quinoline Yellow, CI 47005) and of other sulfonated dyes such as FD&C Yellow No. 6 (Sunset Yellow, CI 15985) and D&C Green No. 8 (Pyranine Concentrated, CI 59040). A general approach to the separation of dyes by HSCCC is presented in Figure 1.

Instrumentation

For the separation of dyes, both by conventional and pH-zone-refining CCC, commercially available high speed CCC centrifuges are used. Such instruments are described in the HSCCC entry in this volume. The separations described below were performed with HSCCC systems from PC, Potomac, MD, USA and Pharma-Tech Research, Baltimore, MD, USA. A schematic diagram of a HSCCC system used for separation of dyes is shown in Figure 2.

Conventional HSCCC

Conventional HSCCC may be applied only to the separation of relatively small amounts (up to several hundred milligrams when the common 325 mL volume column is used) of dye mixtures. In contrast to pH-zone-refining CCC, conventional HSCCC also permits separation of nonionic components. Analytical size separations (less than 10–20 mg of an ionic or nonionic component of interest) should be performed by conventional HSCCC.

Selection of the Solvent System

The solvent system used for a conventional HSCCC separation is selected according to the hydrophobicity

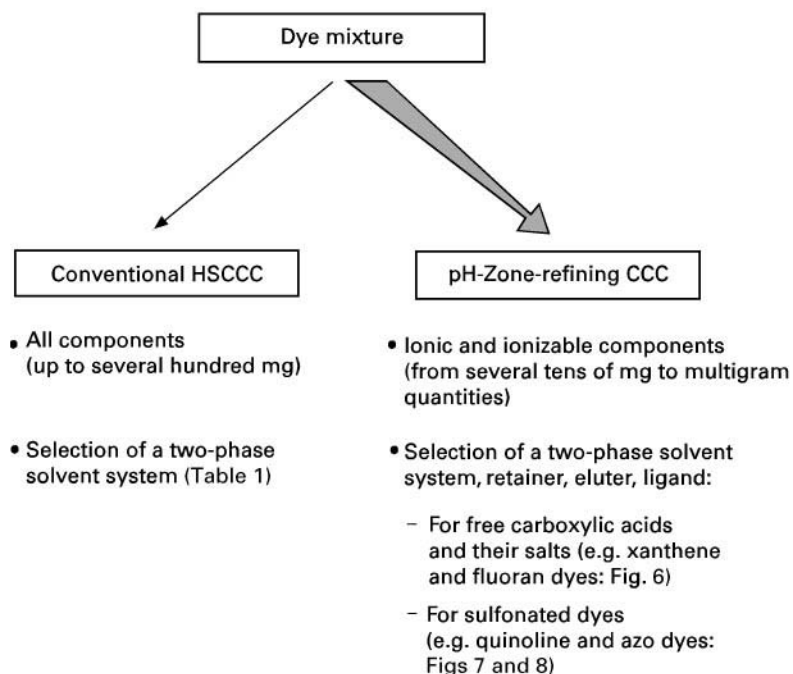

Figure 1 General approach to the preparative separation of dyes by HSCCC.

of the targeted components so that the respective partition coefficients (K) of these components are close to 1. **Table 1** summarizes the solvent systems used for specific dye separations. Also listed in **Table 1** are the general requirements for the selection of a solvent system. The procedures for a systematic search for a suitable solvent system have been discussed previously.

Separation Procedure

The separation is initiated by filling the column with the stationary phase (usually the upper organic phase of the biphasic solvent system) using the liquid

chromatography pump (Figure 2). The sample to be separated, dissolved in a minimum volume of the solvent system (equal volumes of each phase), is then loaded into the column through the sample injection valve (which facilitates the elimination of air bubbles) by syringe or with pressurized nitrogen (60 psi). The mobile phase is then pumped into the column while the column is rotated (usually at 3 mL min^{-1} and 800 rpm). The effluent is passed through a UV-visible detector, and fractions of 3 or 6 mL per test tube are collected with the aid of a fraction collector. The fractions obtained from the HSCCC separation are then further analysed (e.g. by HPLC).

Figure 2 Schematic presentation of a HSCCC system.

Table 1 Selection of a two-phase solvent system for conventional HSCCC of dyes*Reported solvent systems*

Methyl Violet 2B (CHCl_3 -AcOH-0.1 mol L⁻¹ HCl (2 : 2 : 1))
 Sulforhodamine B (*n*-BuOH-0.01 mol L⁻¹ aq trifluoroacetic acid (1 : 1))
 Gardenia Yellow (EtOAc-*n*-BuOH-H₂O (2 : 3 : 5))
 Azo-dyes (acid, direct and disperse azo-dyes)
 Phloxine B (CI 45410) (EtOAc-*n*-BuOH-0.01 mol L⁻¹ aq NH₄OAc (1 : 1 : 2))
 Brominated tetrachlorofluoresceins (EtOAc-*n*-BuOH-0.01 mol L⁻¹ aq NH₄OAc (1 : 1 : 2))

New solvent systems: general requirements

Settling time shorter than 30 s
 Partition coefficient (*K*) close to 1 and should be different for each component of the dye mixture
 Solvent system should provide nearly equal volumes of upper and lower phases

Applications

Table 1 summarizes the applications of conventional HSCCC to the separation of components from synthetic and natural dye mixtures. Figures 3 and 4 show two examples in which this technique was successfully applied to the separation of dye mixtures.

Oka *et al.* employed conventional HSCCC to separate the main components from the gardenia fruit extract (*Gardenia jasminoides* Ellis) used extensively in Japan as a food colour additive under the name Gardenia Yellow (Figure 3). The solvent system used for the separation, ethyl acetate-*n*-butanol-water (2 : 3 : 5), was chosen based on the partition coefficient (*K*) of each of the 14 components, as determined by HPLC. Figure 3A shows the HPLC analysis of the original mixture. The chromatogram obtained for the separation of the three main components (geniposide, *trans*-crocin and 13-*cis*-crocin) from a 25 mg portion of Gardenia Yellow by conventional HSCCC, using the upper organic layer as the stationary phase, is shown in Figure 3B.

Figure 4 shows the chromatogram obtained by Fales *et al.* for the HSCCC separation of the components of a 6 mg portion of the triphenylmethane dye Methyl Violet 2B, composed of a mixture of *N*-methylated forms of pararosaniline. The solvent system used in this case, CHCl_3 -acetic acid-0.1 mol L⁻¹ HCl (2 : 2 : 1), succeeded in separating the various methylated homologues and several contaminants. For this separation, the aqueous layer was used as the stationary phase. The proposed structures of the separated components and of one of the isolated contaminants (mol.wt 491; Figure 4) are based on their ²⁵²Cf plasma desorption mass spectra.

pH-Zone-Refining CCC

pH-zone-refining CCC can only be applied to the separation of ionic or ionizable components. The

principles of this technique are discussed in this volume. Ideally, the sample components should be stable over a wide pH range, from 1 to 10 for dyes containing a carboxylic acid group and from 0.5 to 13.5 for sulfonated dyes. The quantity of each targeted component in the sample mixture must be at least 0.1 mmol and preferably over 1 mmol. Depending on the solubility of the sample mixture in the solvent system, multi-gram quantities of dyes can be separated in one experiment using a typical preparative column of approximately 325 mL capacity. A general approach to the separation of dyes by pH-zone-refining CCC is presented in Figure 5. This method is applied to the separation of dyes containing carboxylic acid groups (e.g. xanthene dyes or their lactone analogues, fluoran dyes) by using an organic acid (e.g. trifluoroacetic acid, TFA) as a retainer in the organic stationary phase and a base (e.g. ammonia) as an eluter in the aqueous mobile phase. Compounds containing one or more amine groups (e.g. Methyl Violet 2B) may also be separated by pH-zone-refining CCC by using an organic base as a retainer (e.g. triethylamine) and an inorganic acid as an eluter (e.g. HCl), as described elsewhere in the present volume.

The more polar sulfonated dyes can be separated by affinity-ligand pH-zone-refining CCC (right column in Figure 5), in which case a ligand is added to enhance the partitioning of the dye components into the organic stationary phase.

Selection of the Solvent System

The process of selecting a solvent system for pH-zone-refining CCC separations is very different from that conducted when selecting a solvent system for conventional HSCCC separations. For most pH-zone-refining CCC separations, a suitable solvent system can be found by testing various volume ratios of ether (diethyl or methyl-*tert*-butyl, MTBE)-acetonitrile (CH_3CN)-water. To the chosen system, an or-

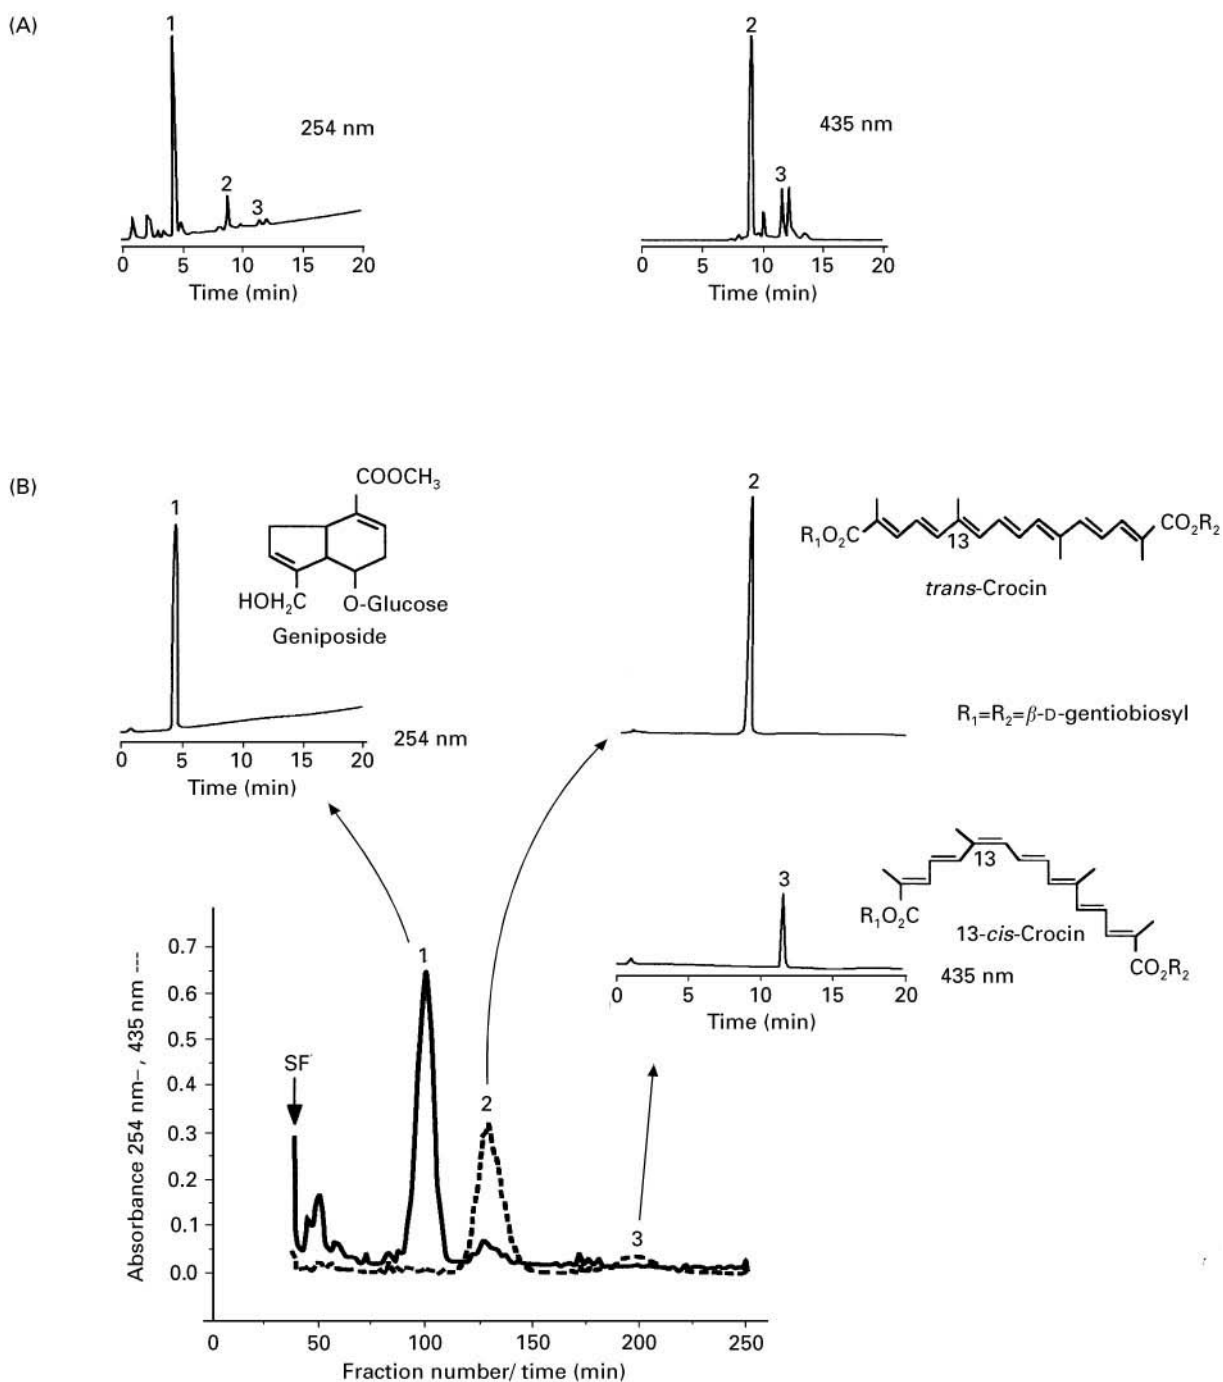

Figure 3 Separation by conventional HSCCC of components from a sample of the Japanese food colour additive Gardenia Yellow. (A) High performance liquid chromatograms at 254 nm and 435 nm of the original sample. (B) Conventional HSCCC for the separation of a 25 mg portion of the sample and the HPLC chromatograms of the separated components. Experimental conditions: solvent system: ethyl acetate-*n*-butanol-water (2:3:5 by volume). The aqueous phase was used as mobile phase. Sample: 25 mg Gardenia Yellow dissolved in 2 mL solvent (1 mL of each phase). Flow rate: 2 mL min⁻¹ in the head-to-tail elution mode. Detection: 254 (continuous line) and 435 nm (dashed line). Speed of revolution: 800 rpm. Stationary-phase retention: 65.8%. SF, Solvent front. (Oka *et al.*, 1995 with modifications.)

ganic acid (TFA) is added to the organic layer as a retainer and an inorganic base such as ammonia is added to the aqueous layer as an eluter if dyes containing carboxylic acid groups are to be separated.

For the separation of dyes containing amino groups, an organic base (such as triethylamine) is added to the organic stationary phase as a retainer and an inorganic acid (HCl) is added to the aqueous

Figure 4 Separation by conventional HSCCC of components from a sample of Methyl Violet 2B. Experimental conditions: Solvent system: chloroform–acetic acid–0.1 mol L⁻¹ HCl (2 : 2 : 1 by volume). The organic phase was used as mobile phase. Sample: 6 mg Methyl Violet 2B dissolved in 5 mL organic phase. Flow rate: 4 mL min⁻¹ in the head-to-tail elution mode. Speed of revolution: 800 rpm. (Fales *et al.*, 1985 with modifications.)

mobile phase as an eluter. For affinity-ligand pH-zone-refining CCC separations (for sulfonated dyes), a ligand is added to the stationary phase to retain the sulfonated dyes in the column by enhancing their partitioning into the organic stationary phase.

Standard pH-zone-refining CCC The following steps are recommended for the selection of an appro-

priate two-phase solvent system for the separation by standard pH-zone-refining CCC of a dye containing a carboxylic acid group (summarized in **Figure 6**):

1. Prepare a two-phase solvent system by thoroughly equilibrating water and either MTBE or diethyl ether in a separatory funnel at room temperature.

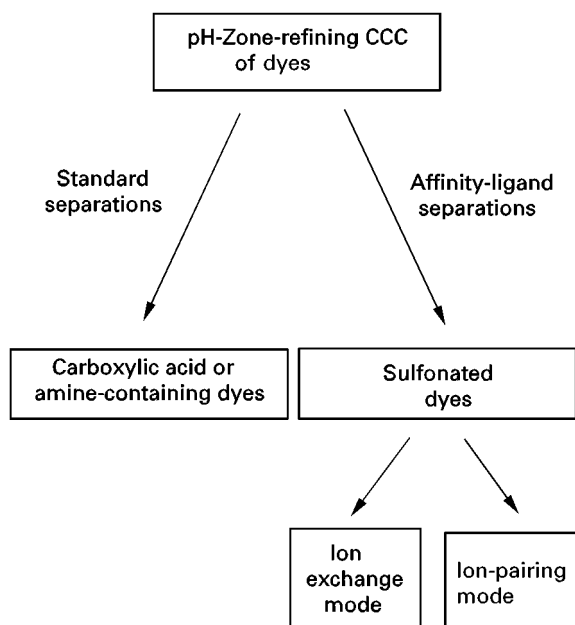

Figure 5 General approach to the separation of dyes by pH-zone-refining CCC. (Reproduced from Fales *et al.*, 1985 with permission from the American Chemical Society.)

2. Deliver a 2 mL aliquot of the upper (U) and of the lower (L) phase into a test tube. Add a very small amount of dye and agitate to equilibrate the contents.
3. Add a small amount of aqueous ammonia ($\approx 28\%$; eluter) to the mixture (to give a base concentration of approximately 12 mmol L^{-1} , pH 10) and equilibrate the mixture. If almost all the colour visibly partitions into the lower aqueous phase, then the partition coefficient $K_{\text{base}}(\text{U/L}) \ll 1$. If visual assessment is unclear, K_{base} may be determined by spectrophotometry. Dilute an aliquot from each phase with solvent

(e.g. methanol) and measure the absorbance at an appropriate wavelength using a spectrophotometer. Obtain the partition coefficient, $K_{\text{base}}(\text{U/L})$, by dividing the absorbance of the dye in the upper phase by that in the lower phase.

4. If $K_{\text{base}} \geq 0.5$, the above test should be repeated with a less polar (more hydrophobic) solvent system such as *n*-hexane–ethyl acetate–methanol–water (1:1:1:1).
5. If $K_{\text{base}} \ll 1$, add retainer acid TFA (approximately 20 mmol L^{-1}) to the mixture to bring the pH to approximately 2, and re-equilibrate the mixture by agitation. Using procedure 3, obtain K_{acid} . If $K_{\text{acid}} \gg 1$, the solvent system can be effectively used to separate the sample components.
6. If $K_{\text{acid}} \leq 2$, the above tests should be repeated with a more polar (more hydrophilic) solvent system such as *n*-butanol–water.

For amine-containing dyes, substitute HCl for ammonia in step 3 above to obtain $K_{\text{acid}} \ll 1$ and substitute triethylamine for TFA in step 5 above to obtain $K_{\text{base}} \gg 1$.

Affinity-ligand separations Sulfonated dyes are much more polar (hydrophilic) compounds than the carboxylic acid dyes. They tend to distribute predominantly in the aqueous phase of a conventional two-phase solvent system, even if the aqueous phase is highly acidic. For the separation of sulfonated dyes by pH-zone-refining CCC, the addition of a hydrophobic ligand is necessary in order to retain the dyes in the organic stationary phase. Two kinds of ligands were used successfully for the separation of sulfonated dyes: ion exchange reagents (e.g. dodecylamine, tridodecylamine), which are always retained in the organic stationary phase, and

Figure 6 Conditions required for the separation of dyes containing carboxylic acid groups by pH-zone-refining CCC. For conditions required for the separation of dyes containing amino groups, see text.

Figure 7 Conditions required for the separation of sulfonated dyes by affinity-ligand pH-zone-refining CCC in the ion exchange mode.

ion-pairing reagents (e.g. tetrabutylammonium hydroxide), which partition into either phase. These ligands are dissolved in the organic phase (stationary phase and/or sample solution) at a concentration determined in preliminary experiments.

Ion exchange mode separations (Figure 7) The following steps are recommended for the selection of an appropriate two-phase solvent system for the separation of sulfonated dyes by affinity-ligand pH-zone-refining CCC in the ion exchange mode:

1. Prepare a two-phase solvent system composed of either MTBE- CH_3CN -water at a volume ratio of 2:2:3 (used for the separation of the main component from FD&C Yellow No. 6, Sunset Yellow, CI 15985) or iso-amyl alcohol (iAA)-MTBE- CH_3CN -water at volume ratios from 3:1:1:5 to 3:5:1:7 (used for the separation of mono-, di- and trisulfonated components of Quinoline Yellow, CI 47005).
2. Deliver a 2 mL aliquot of the upper (U) and of the lower (L) phase into a test tube. Add a small amount of dye and agitate to equilibrate the contents.
3. Add a small amount of ion exchange reagent (e.g. dodecylamine, tridodecylamine at 5–20% concentration) and equilibrate the mixture by agitation.
4. Add a small amount of a strong inorganic acid (e.g. HCl , H_2SO_4 at 3–4%, pH 0.8). Measure the K_{acid} as above.
5. If $K_{\text{acid}} \leq 5$, add more acid and retest.
6. If $K_{\text{acid}} \gg 1$, add eluter NH_3 (28% aq NH_3) to the mixture to give a base concentration of approximately 110 mmol L^{-1} and a pH of 11. Re-equilibrate

the contents. Measure the K_{base} as above. If $K_{\text{base}} \ll 1$, the solvent composition is adequate for separation.

7. If $K_{\text{base}} \geq 0.2$, add more base and retest.

A concentration of 5% ligand (dodecylamine) in the stationary phase was used for the separation of the monosulfonated components of D&C Yellow No. 10, while a higher concentration (up to 20%) of ligand was required for the separation of the di- and trisulfonated components from Quinoline Yellow (including Yellow No. 203).

Ion-pairing mode separations (Figure 8) The following steps are recommended for the selection of an appropriate two-phase solvent system for the separation of sulfonated dyes by affinity-ligand pH-zone-refining CCC in the ion-pairing mode:

1. Follow steps 1 and 2 as described above for the ion exchange mode separations.
2. Add a small amount of ion-pairing reagent (tetrabutylammonium hydroxide, TBAOH, 40% weight solution in water, 0.4 mmol) to give a concentration of approximately 100 mmol L^{-1} and a pH of 12.8. Equilibrate the mixture by agitation. Measure the partition coefficient K_{base} as described above.
3. If $K_{\text{base}} \leq 5$, add more ion-pairing reagent and retest.
4. If $K_{\text{base}} \gg 1$, add an organic acid, TFA (eluter), to give an acid concentration of approximately 80 mmol L^{-1} and a pH of 1.6. Re-equilibrate the mixture by agitation. Measure the partition coefficient K as above. If $K_{\text{acid}} \ll 1$, the solvent composition is adequate for separation.

Figure 8 Conditions required for the separation of sulfonated dyes by affinity-ligand pH-zone-refining CCC in the ion-pairing mode.

5. If K_{acid} is not small enough (greater than 0.2), add more TFA and retest.

Separation Procedure

Standard pH-zone-refining CCC A standard separation is initiated by completely filling the column with the acidified (or basified) organic stationary phase using the liquid chromatography pump (Figure 2). Then the sample solution is loaded into the column through the sample injection valve by syringe or with pressurized nitrogen (60–80 psi). When dyes that contain a carboxylic group are separated, the sample solution is prepared as follows: the sample is dissolved in the organic stationary phase containing the retainer (TFA) and a smaller amount of aqueous lower phase (free of eluter). The sample solution should have a low pH, thus ensuring that the target dye is distributed into the upper (stationary) phase of the sample solution. It is desirable that the sample be completely dissolved in the sample solution. If the sample does not dissolve completely in the sample solution, it can be loaded into the column if it can be homogenized into a fine suspension by sonication for a short time. Ideally, the volume of the sample solution should not exceed 100–140 mL for a preparative separation column of 325 mL capacity. After the sample solution is loaded into the column, the mobile phase containing the eluter (basified aqueous phase) is then pumped (usually at 3 mL min^{-1}) into the column while the column is rotated (800–1000 rpm). The effluent is passed through a UV-visible detector flow cell that is further connected to a pH flow cell (for continuous pH monitoring; alternatively, the pH of each collected fraction is manually recorded with a pH meter) and fractions – usually 3 mL per test tube – are collected with a fraction collector.

Affinity-ligand pH-zone-refining CCC Ion exchange mode A separation is initiated by completely filling the column with ligand-free stationary phase (upper organic phase) by using the liquid chromatography pump. Approximately 100 mL of ligand-containing stationary phase is pumped into the column, thereby displacing part of the column contents. Then the sample solution is loaded into the column through the sample injection valve by syringe or with pressurized nitrogen (60–80 psi). The sample solution is prepared as follows: the sample is dissolved in lower aqueous phase (e.g. 60 mL for 5 g of Quinoline Yellow) and mixed with stationary phase (60 mL) containing the ligand. The sulfonated dyes are brought into the upper phase of the sample solution by the cautious addition of H_2SO_4 (95–98%, 2.2 mL), at which point the pH of the sample solution is approximately 0.8.

After the sample solution is loaded into the column, the aqueous mobile phase containing the basic eluter is pumped through the rotating column as described above for performing standard pH-zone-refining CCC. If carryover of the stationary phase occurs, the elution is stopped (after approximately 60 mL of stationary phase has been eluted) while the rotation of the column is continued. After 3–4 h of rotation, the elution of the mobile phase is restarted, and usually no more carryover of the stationary phase is observed.

Ion-pairing mode A separation is initiated by completely filling the column with ligand-free stationary phase (upper organic phase) by using the liquid chromatography pump. The sample solution is then loaded into the column through the sample injection valve by syringe or with pressurized nitrogen (60–80 psi). The sample solution is prepared as follows: the sample is dissolved in lower aqueous phase.

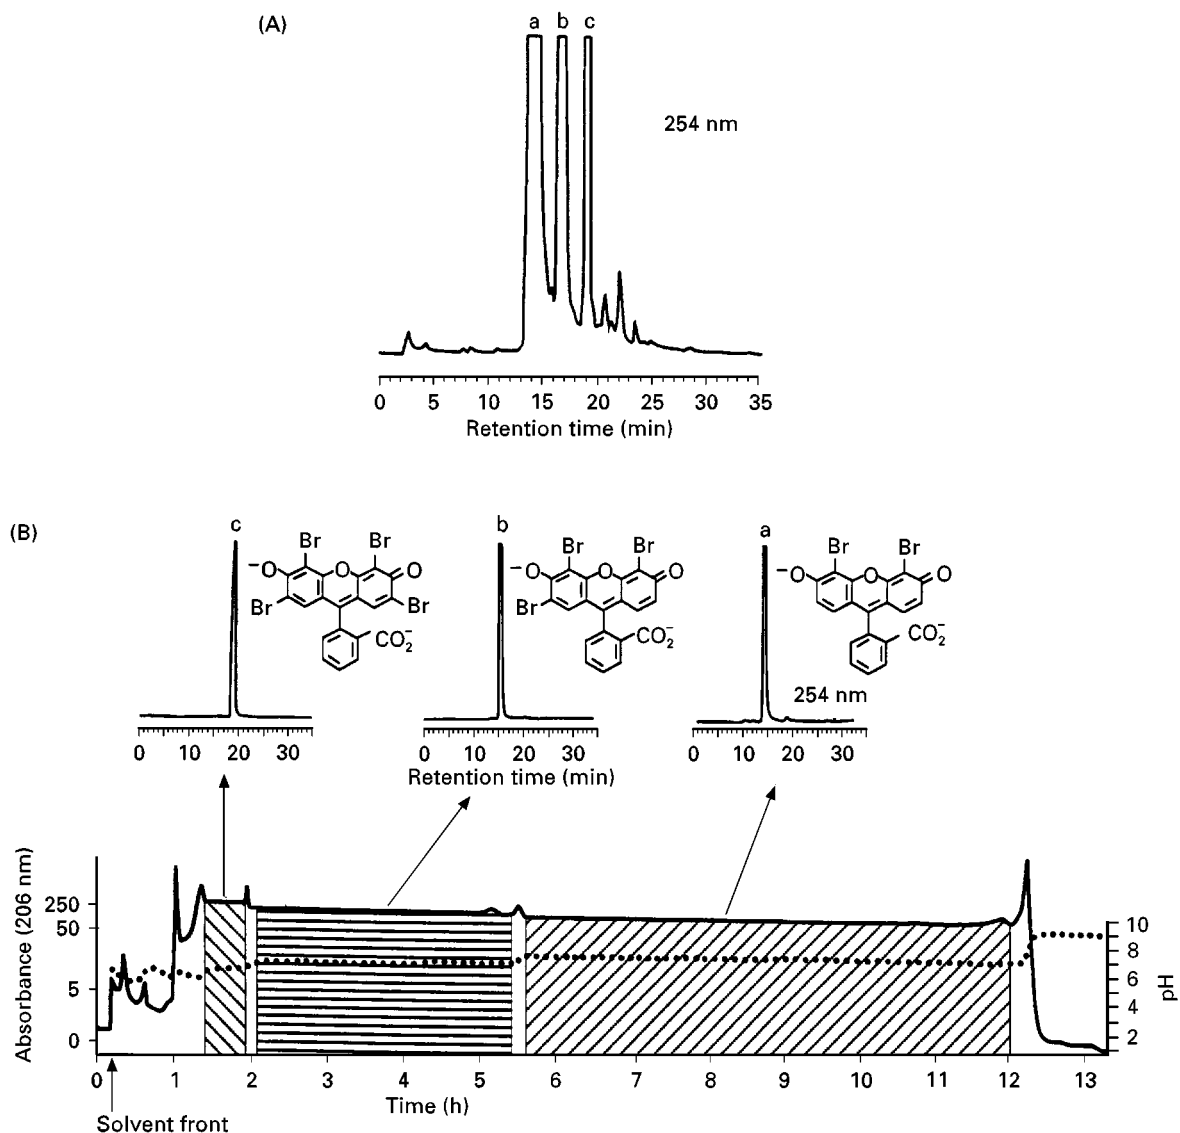

Figure 9 Separation by standard pH-zone-refining CCC of components from the colour additive D&C Orange No. 5 (CI 45370: 1). (A) HPLC analysis of the original sample. (B) pH-zone-refining CCC of the separation and the HPLC chromatograms of the separated components. Continuous line, absorbance (206 nm); dotted line, pH. Experimental conditions: solvent system: diethyl ether–acetonitrile–0.01 mol L⁻¹ aqueous ammonium acetate adjusted to pH 9 with aqueous NH₃ (4 : 1 : 5 by volume). The aqueous phase was used as mobile phase. Sample: 5 g D&C Orange No. 5 suspended in 80 mL solvent system (40 mL each of the upper and lower phases). TFA 200 µL was added to the sample solution as a retainer. Flow rate: 3 mL min⁻¹ in the head-to-tail elution mode. Speed of revolution: 800 rpm. Detection: 206 nm. (Weisz *et al.*, 1994 with modifications.)

To this solution an equal volume of upper phase that contains approximately 100 mmol L⁻¹ of the ion-pairing reagent (TBAOH) is added. The pH of the sample solution is approximately 12.8, and the dye partitions mostly into the upper phase. After the sample solution is loaded into the column, the mobile phase, consisting of the aqueous lower phase and 80 mmol L⁻¹ TFA as an acid eluter, is pumped through the rotating column as described above for standard pH-zone-refining CCC. The pH of the mobile phase is approximately 1.6. If carryover of the

stationary phase occurs, follow the directions given above for the ion exchange mode separation.

Applications

Figures 9–13 show successful applications of pH-zone-refining CCC to the preparative separation of components of fluorescein and sulfonated dyes.

Top: HPLC analysis of the combined fractions 220–246 from the separation in Figure 12. Bottom: reconstructed pH-zone-refining CCC of the separation and HPLC analyses of the separated components. Experimental conditions: solvent system: iso-amyl alcohol-methyl-*tert*-butyl ether-acetonitrile-water (3:4:1:7 by volume). Stationary phase: upper phase. Mobile phase: lower phase to which was added TFA (80.7 mmol L⁻¹, pH 1.6). Sample solution: 0.55 g of residue from combined fractions 220–246 from the separation in Figure 12 dissolved in 30 mL of solvent system (15 mL each of lower and upper phases), to which was added tetrabutylammonium hydroxide (100 mmol L⁻¹). The pH of the sample solution (light line, top) became 12.8 and the dye partitioned mostly in the upper phase. Flow rate: 3 mL min⁻¹. Speed of revolution: 825 rpm. Detection: 516 nm (bold line). Retention of the stationary phase: 75%. Time of the separation: 2.5 h.

of higher halogenated dyes (e.g. Phloxine B, Rose Bengal), and its contaminants can be carried over during the manufacturing process. Two of the isolated contaminants (e and f) had not been reported previously.

Affinity-ligand pH-zone-refining CCC separations
Ion exchange mode Figure 12 shows the separation of a 5 g portion of the Japanese colour additive Yellow No. 203 (Quinoline Yellow, CI 47005) with the ion exchange reagent dodecylamine as the retainer in the stationary phase at a concentration of 20%. To retain the stationary phase in the column, at the point in the separation when the column contains approximately 50% of the mobile and 50% of the stationary phase, reduce the flow rate of the mobile phase to one-fifth of the original flow rate (i.e. 0.6 mL min^{-1} instead of 3 mL min^{-1}) for several hours, and then the flow rate is increased to its original value. This procedure results in a satisfactory retention of the stationary phase of 36.1% (measured at the end of the separation). A good separation was obtained for two major components, c and b. The first few fractions containing c were contaminated with component a (not shown in Figure 12). Two other components (d and e) eluted together, as shown by the associated HPLC chromatograms in Figure 12.

Ion-pairing mode By using an ion-pairing reagent (TBAOH) as the retainer in the sample solution containing the two components of Yellow No. 203 (0.55 g) that eluted together in Figure 12, d and e were well-separated, as shown in Figure 13. Compound d is a newly identified disulfonated positional isomer of Quinoline Yellow. The results presented in Figures 12 and 13 for the separation of the components of Yellow No. 203 demonstrate that the ion exchange and ion-pairing modes can complement each other.

Conclusion

HSCCC has been used to accomplish the difficult task of separating and/or purifying multi-gram amounts of dyes containing either sulfonic or carboxylic acid groups. No other preparative-scale chromatographic separation of multi-gram quantities of these dyes has been previously reported. It is envisioned that HSCCC could be scaled up to separate kilogram quantities of dyes through modifications of the instrumentation. The availability of large quantities of highly purified dyes will have many benefits, such as enabling standardization of biological stains and lowering the cost of the ultra-pure laser-quality dyes.

Introduction

Natural dyes are organic matter made up of coloured compounds originating from natural living sources such as plants and animals. These compounds can be found either directly in the extracts or become coloured by hydrolysis, oxidation, condensation, etc., from extracted colourless precursors. Some of them change colour following such reactions or by complexation with certain metallic cations.

These dyestuffs are generally employed for dyeing fibres and fabrics (usually protein and cellulosic), staining several organic and mineral materials (histological preparations, wood, hair, feathers, Easter egg shells), producing organic pigments (painting, printing) and colouring of food, beverages, cosmetics and pharmaceutical products. They are used in analytical chemistry as well as acid–base indicators or complexation agents. A large number of naturally occurring coloured substances are chemically labile. This excludes their direct use principally because of poor light-fastness. Some dyestuffs, in addition to their colouring qualities, have therapeutic properties like regulation of metabolism, anti-inflammatory treatment and anti-cancer prevention among others.

Used frequently around the world in traditional societies, starting probably from the Stone Age, natural dyes were rapidly replaced by synthetic dyes from the second half of the nineteenth century onwards. Nowadays, natural dyes have a growing importance in our lives since almost all of them are hypoallergenic and nontoxic for humans, which is a significant advantage over many synthetic dyes.

Chemical classification of dyestuffs follows the general arrangement of organic compounds and

depends on the generic, basic structure. There are over 20 family structures which many hundreds of compounds belong to. Examples of the most frequently encountered structures are shown in **Table 1**.

The most important application of dyes, from a historical point of view, is textile dyeing. For this reason, the most common classification of dyestuffs is determined by their dyeing properties and dyeing technology. According to their dyeing properties, natural dyes belong to four principal groups: direct dyes (e.g. curcumin, a diaryloylmethane from *Curcuma longa*), mordant dyes (e.g. alizarin and other anthraquinones from various madders), reactive dyes (e.g. depsides and depsidones from lichens) and vat dyes (e.g. indigotine from indigo, woad, dyer's knotweed and others).

Membership to one of the dye families is determined by the type of 'connection' between colorant and support. However, many dyestuffs may show more than one dyeing mechanism, simultaneously or according to applied dyeing conditions. The type of connection determines the method of liberation of dyestuff prior to analysis. Identification of type and origin of dyestuffs requires an understanding of composition.

Extraction

Direct Raw Material Extraction

Many natural dyestuffs or their precursors (e.g. indican and isatan B for indigotine) are water-soluble. Their extraction from raw plant or animal material can be achieved by water, sometimes heated to facilitate penetration into the cells. This process, along with possible cell destruction, can also be accelerated by the use of an ultrasound bath. In several cases, the addition of water-miscible solvents (e.g. methanol, ethanol or acetonitrile) improves the recovery of relatively hydrophobic compounds, such as curcumin, certain anthraquinones, etc. Moderately polar solvents

Table 1 Some important chemical families of dyestuffs

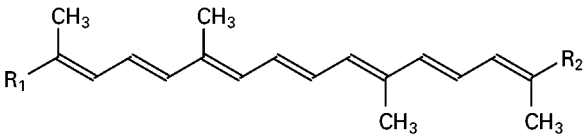

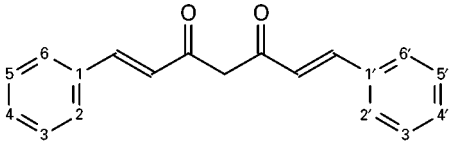

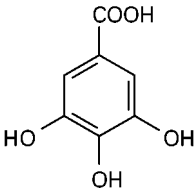

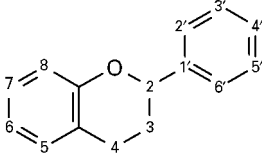

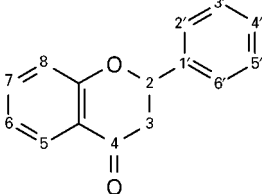

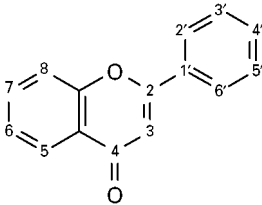

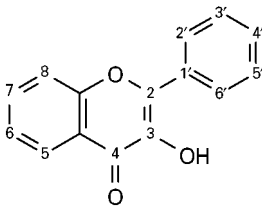

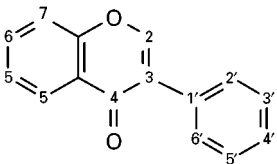

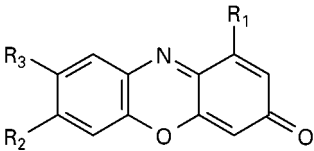

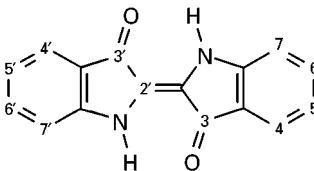

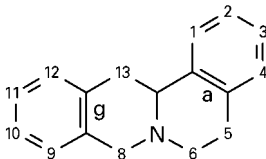

Generic name	Generic structure	Example	
		Name	Usual name
Carotenoid		Carotenoid-dicarboxylic acid ($R_1, R_2 = \text{COOH}$)	Crocin
Diarylmethane		Diferuoylmethane (4,4' = -OH, 5,5' = -OMe)	Curcumine
Gallotannin		Digaloylhamamelose	Hamamelitannin
Flavane		3,3',4',5,7-Pentahydroxyflavane	Catechin
Flavanone		3,3',4',7-Tetrahydroxyflavanone	Fustin
Flavone		4',5,7-Trihydroxyflavone	Apigenin
Flavonol		3,4',5,7-Tetrahydroxyflavone	Kaempferol
Isoflavone		3',4',5-Trihydroxy-7-methoxyisoflavone	Santal

Table 1 *Continued*

Generic name	Generic structure	Example	
		Name	Usual name
Homoisoflavone		3,4',5',7-Tetrahydrohomoisoflavone	Sappanon A
Chalcone		3,4,4',5,6'-Pentahydroxychalcone	Robtein
Aurone		3',4',6-Trihydroxyaurone-6-glucoside	Sulfurein
Benzoquinone		3,6-Dihydroxy-2,5-di(p-hydroxyphenyl) benzoquinone	Atromentine
Naphthoquinone		2-Hydroxynaphtoquinone	Lawsone
Coumarin		7,8-Dihydroxycoumarin-7-β-D-glucoside	Daphnin
Anthraquinone		1,3-Hydroxy-2-carboxyanthraquinone	Munjistin
Xanthone		1,7-Dihydroxy-9H-xanthen-9-on-7-D-glucuronide	Euxanthic acid

Table 1 Continued

Generic name	Generic structure	Example	
		Name	Usual name
Phenoxazone		α -Aminoorcein ($R_1 = \text{Me}$, $R_2 = \text{NH}_2$, $R_3 = \text{orcinol}$)	Orcein ^a
Indole		6,6'-Dibromoindigotine	Purple ^a
Berberine		5,6-Dihydro-3-hydroxy-2,9,10-trimethoxy dibenzo[a,g]quinolizinium hydroxide	Berberine

^aThe name of a natural mixture of related compounds. It's applied here when the particular usual name of the compound does not exist.

such as ethyl acetate have been proposed for general extraction purposes. The choice of extraction solvent and conditions affects the quantitative aspects of dyestuff analysis.

Even the use of water, and especially warm water – traditionally used for the recovery of colouring matter – may also introduce composition changes. Many natural dyestuffs are heterosides (gluco-, rhamno-, primeverosides and other) and can become aglycone forms through the action of enzymes (e.g. glucosidases) present in living organisms. Their activity can be inhibited either by excessive heating (boiling) or by the addition of denaturation factors (alcohols, strong electrolytes).

For quantification purposes, especially in pharmaceutical and cosmetic laboratories, extracts are analysed after acid hydrolysis. The hydrolysis of heterosides transforms them into related aglycones (e.g. ruberythric acid to alizarin). This treatment simplifies the chromatogram, because one aglycone can be obtained from several monosaccharide or disaccharide derivatives and the number of chromatographic peaks decreases (Figure 1).

Coloured Matter Samples Extraction

Acid hydrolysis has remained a quasi-universal method of natural dyestuff extraction from dyed and stained supports. The extraction medium is usually composed of an aqueous mineral acid solution (e.g. HCl or H₂SO₄), sometimes with the addition of meth-

anol to prevent possible precipitation of some compounds. This hydrolysis destroys chemical ionic and coordination links between dye molecules and support or mordant complexes. Fixed extraction conditions are the goal of repetitive results, because of possible partial structural change or destruction of several compounds. In applied acid solutions a depolymerization of oligomeric and polymeric molecules (e.g. gallotanins to gallic acid, lacmus to orceines) can be observed. The amount of acid usually employed in the extraction medium is also enough to catalyse the oxidation of homoisoflavonoids (e.g. haematein to haematoxylin). The major transformation remains, nevertheless, the aglyconeization of the heterosides. Decomplexation with ligands stronger than the dyestuffs has been proposed to improve the recovery of complex dyes by avoiding hydrolysis of heterosides.

In the special case of a non-soluble matrix, as for organic pigments in drying oil layers from paintings, the direct derivatization with *m*-(trifluoromethyl) phenyltrimethylammonium hydroxide (TMTFTH), followed by methylation of paint medium with boron trifluoride/methanol (BF₃/MeOH) is employed. This method provides good recovery of dyestuffs, principally anthraquinoids. Its main inconvenience is the formation of multiple methylated derivatives for some compounds.

Vat dye constituents are very sparingly soluble in aqueous solutions. Some indigoids are soluble in

Figure 1 Influence of hydrolysis on composition of dyestuff extracted from root of Madder (*Rubia tinctorum* L.). (A) Chromatogram of fresh aqueous extract; (B) the same extract after acid hydrolysis. Compounds: 1 ruberythric acid (β -2-alizarin primeveroside), 2 alizarin, 3 purpurin.

chloroform, but one of them – 6,6'-dibromoindigotine from so called 'true' or 'Tyrian' purple – is well known as a 'soluble-in-nothing' compound. In fact,

for a satisfactory extraction of all compounds from vat dyes, heated pyridine, dimethylformamide (DMF) or dimethyl sulfoxide (DMSO) is necessary. Pyridine

Figure 2 Continued

is quite toxic and apparently destroys alkyl-bonded silica stationary phase when extracts are separated. The indigotins in DMF solutions isomerize to related indirubins with the help of ultraviolet light. DMSO is very viscous and displays mixing problems (known as 'viscous fingering') when the aqueous mobile phase is employed and affects stationary phase efficiency (ranging from poor peak shape to multiple peaks). It appears that DMF is the best medium, under conditions of time- and temperature-controlled extraction, even if its viscosity makes large volume injections difficult.

Chromatography

Mobile Phases

The solubility of natural dyestuffs covers practically the entire range of solvent polarities, from water to *n*-hexane. Still, many of them are soluble in both moderately polar organic solvents (e.g. chloroform) and water. These properties are linked to the compounds' structures. In addition to their generic, low polar, aromatic or isoprene structures, they usually contain polar groups, especially proton-releasing ones such as hydroxyl and carboxyl. Practice shows that the use of water with some organic water-miscible solvents solubilizes almost all classes of dyestuffs.

Such behaviour of natural dyes determines the type of chromatographic system used. Apart from the tentative applications of a normal phase (silica) and a nonpolar eluent, reversed-phase conditions are most often applied.

The solvent system is commonly composed of water, an organic modifier and an ion suppressor or counterion.

Many ion suppression reagents are used to control pH. At pH around 2.5 most dyestuffs are unionized but some basic compounds become ionized (e.g. berberine, which is fortunately rather rarely encountered). The most popular acids are *o*-phosphoric (H_3PO_4) and acetic (CH_3COOH , AcH), but in the case of mass spectrometry (MS) on-line detection they should be replaced by volatile trifluoroacetic acid (TFA). To avoid the formation of poorly soluble salts of basic compounds and/or to improve peak shapes, methanesulfonic acid (MSA) has been proposed (Figure 2, compare A and B).

The use of counterions is less habitual owing to the considerable equilibrium stabilization time needed for the stationary phase in gradient analysis.

Analysis time in both isocratic and gradient elution is usually between 15 to 45 min, depending on the type and the number of compounds requiring separation.

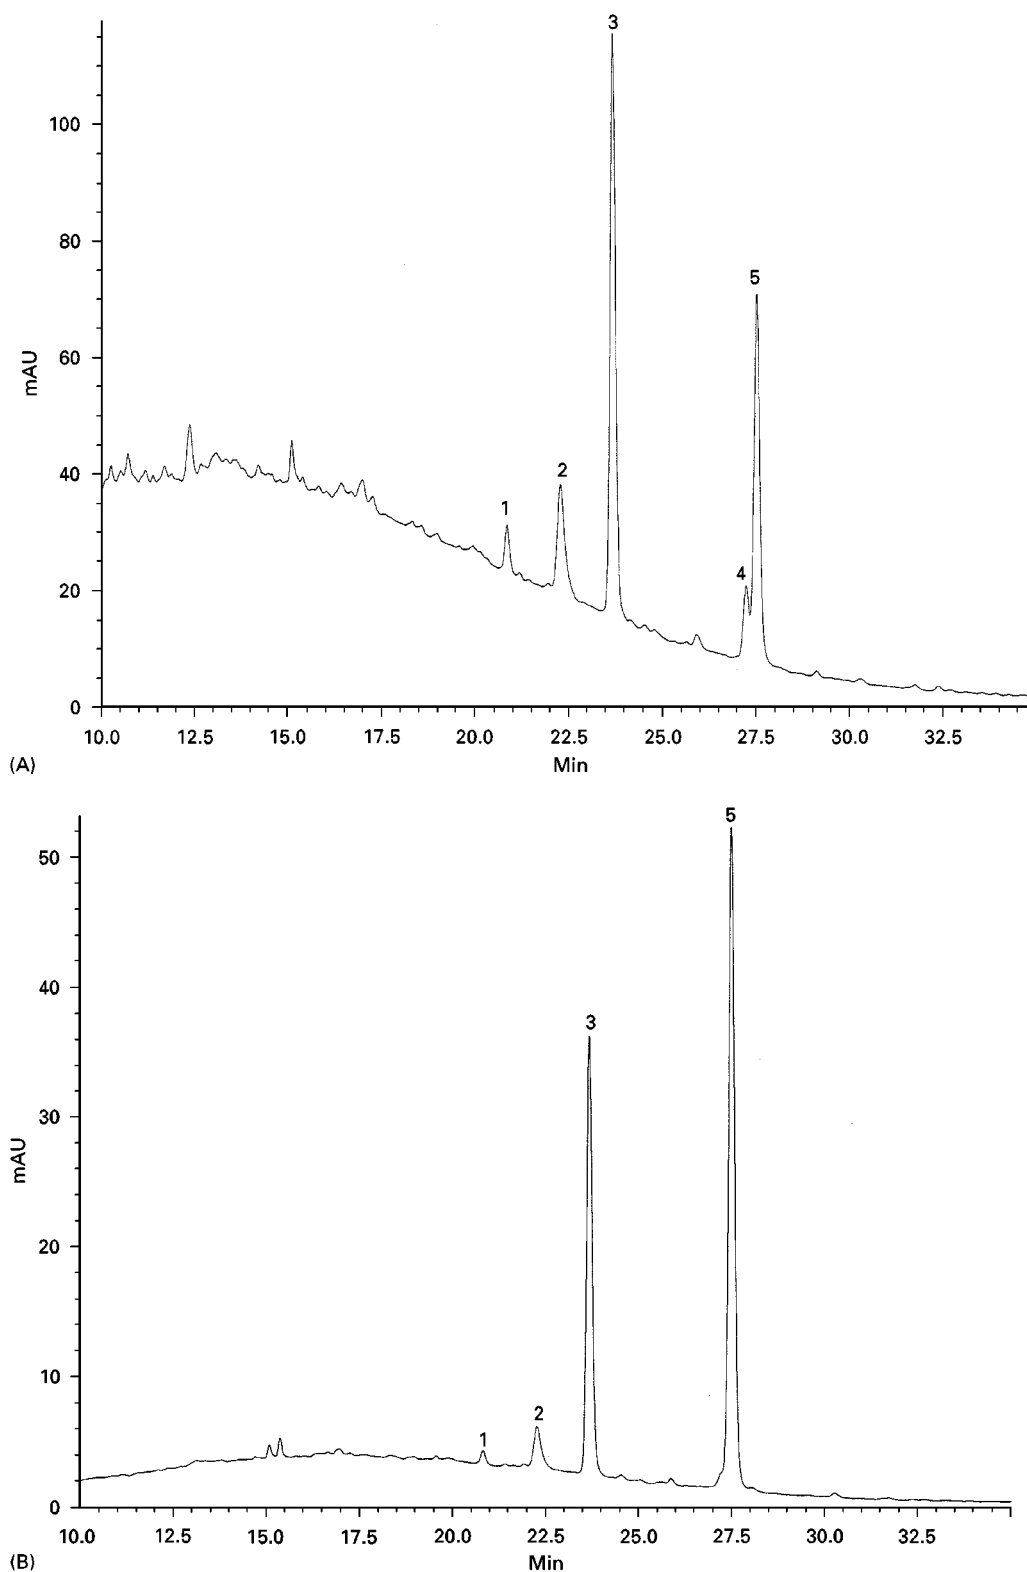

Figure 3 General and selective UV-vis channel detection of violet dyed wool sample (Coptic textile, 6th century). Compounds: 1 anthragallol, 2 pseudopurpurin, 3 alizarin, 4 indigotin, 5 purpurin.

Figure 3 Continued

Stationary Phases

Among the stationary phases used in natural dye-stuffs analysis, the major part of applications is achieved on octadecyl (called RP 18, or C 18) bonded silica. This type of phase is the most versatile; however, different brands bring about important differences in separation characteristics (Figure 2, compare B and C). The octyl (RP 8) and phenyl (Ph) phases have some specific applications and can offer other, sometimes more satisfactory separations than RP 18 in specific cases.

Advances in natural dyes chromatography follow general trends: a growing efficiency of separations and reduced separation time as well as increased sensitivity of detection. This is the reason for the constant testing of the types of stationary phases, and of the rising use of smaller and more uniform particles and also of shorter and narrower columns.

Detection and Identification

Detectors

Dyestuff components show strong selective absorption in the UV-vis spectrum. This effect is responsible for their coloration and makes absorption detection simple. In the case of single or multichannel detectors, the recognition of compounds is based on retention

time and, if possible, on absorption at characteristic wavelengths, usually in the visible (e.g. 360 nm for yellows, 485 nm for reds, 650 nm for blues, etc., with a suitably large bandwidth) (Figure 3). The photodiode array (PDA) gives the possibility of confirmation of compound identity by the corresponding peak spectra (Figure 4).

The principal inconvenience of UV-vis detection is the recognition of only those substances entered as references in the database. Even the PDA gives only partial structure recognition because of limited UV-vis information contained in the spectra and their possible alteration in different mobile phase compositions. New compounds have to be collected at the detector exit and analysed by other, usually spectrometric, methods. This problem can be avoided by application of on-line mass spectrometry, giving more precise information about the molecular structure. An interesting approach to detection can be in-line tandem of PDA and a mass-selective detector (MSD) permitting pre-selection of coloured compounds and thus their detailed analysis.

Sources Recognition Criteria

High-performance liquid chromatography analysis of natural dyes gives an identification of compounds. From this information, as a first step, a chemical class or dyeing group can be deduced. Moreover, the

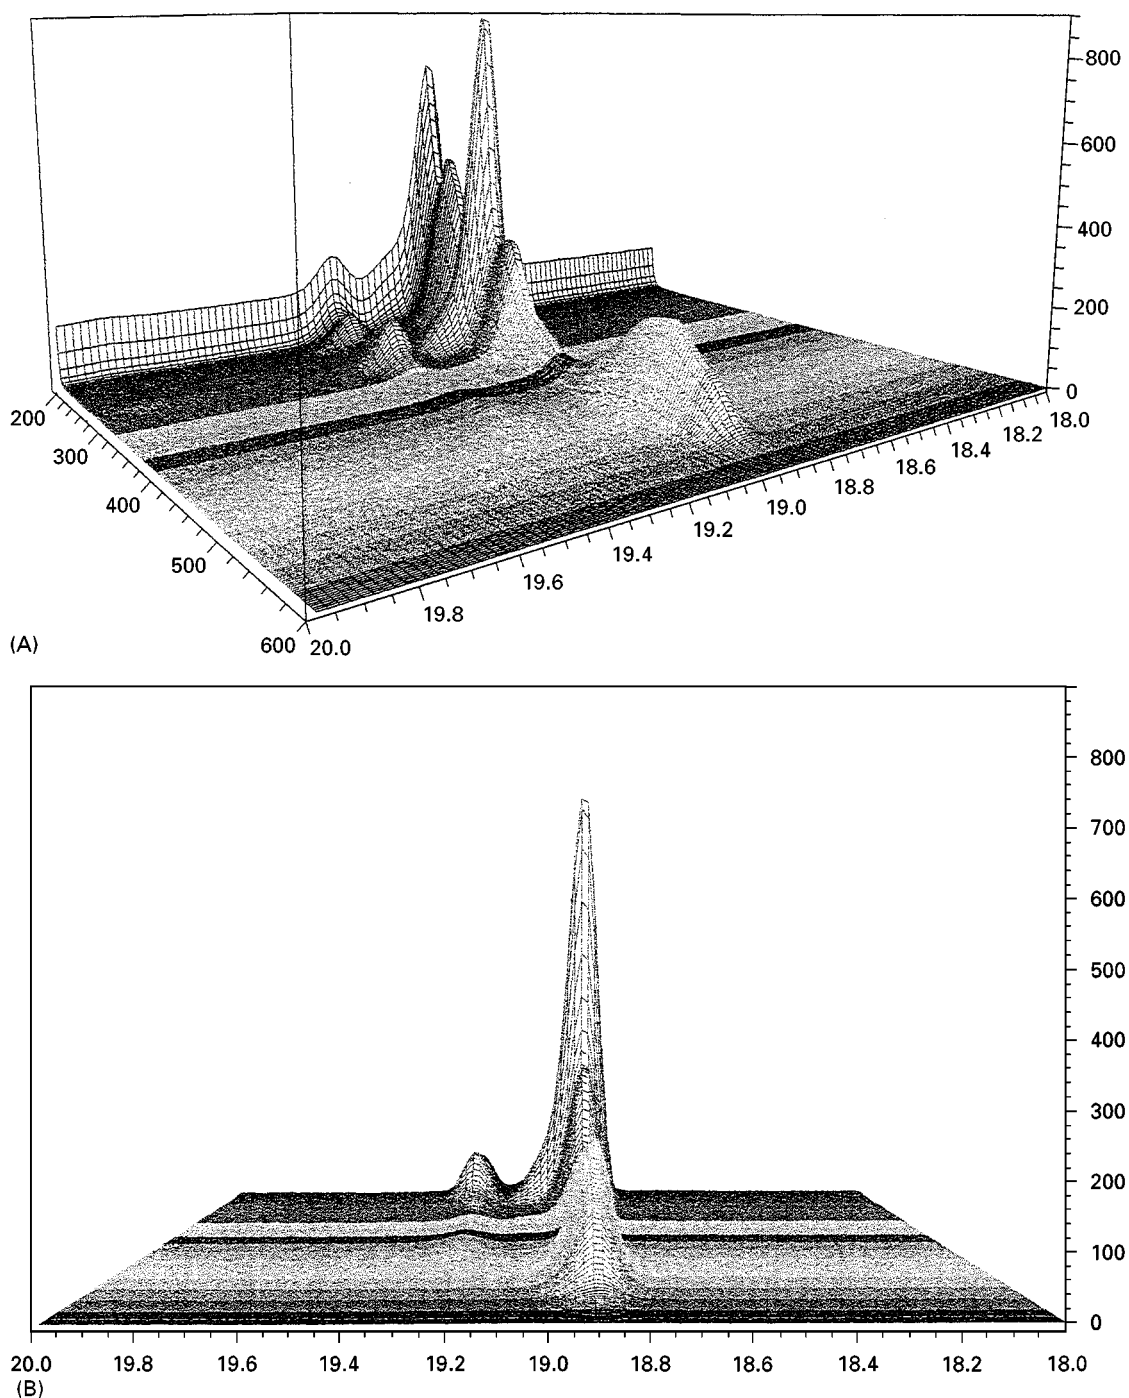

Figure 4 Representation of a fragment of data collected from PAD during the analysis of extract from females of Kermes (*Kermes vermilio* PLANCH). Kermesic acid (higher absorption) and flavokermesic acid (lower absorption). (A) General view (axes: x = time, y = wavelength, z = absorption); (B) Chromatograms cut display (x , z). (C) Spectra cut display (y , z).

qualitative and quantitative information about the compounds detected in a chromatogram can help in dyestuff source recognition. This is the aim of chemotaxonomy, employed for many purposes: in biology, in the history of civilizations, in forensic sciences, etc. In general, analysis of colorants from plant and animal material give a few major and a lot

of minor peaks on chromatograms recorded at the colour-characteristic wavelengths. The corresponding characteristic compounds are adequate for the identification of botanical or zoological phylum, family, subfamily, group or genus, but can also be common for several, quite different species (Figure 5). Species identification is based on the relative

Figure 4 *Continued*

quantity and identity of marker compounds. Their presence or absence is characteristic for only one species. Given the complexity of colorants originating from natural sources, as is the case for other natural substances, sometimes it should be satisfactory to obtain and to compare just their fingerprints.

The chromatographic fingerprints appearance depends on sample preparation, separation conditions and detection principles. That is why the constitution of one's own database containing the results of analysis of reference samples according to established, invariable and repeatable procedure is required.

Extra-Analysis Factors Affecting Dyes Composition

The analytical results obtained from real, coloured objects sometimes show important differences in dye composition in comparison with reference samples from one's own database or published data. These differences limit a clear interpretation and source identification. Such a situation is a result of one or more factors, of which the most important are quantity of sample, method of dyestuff preparation and ageing of the dye.

The quantity of coloured sample necessary for analysis depends on the total contents of the dyestuff

in the sample. In the first approach this can be evaluated as a function of colour intensity. Of course, precise evaluation is more complex and should consider the substrate (or matrix) material properties such as surface-to-mass ratio, parameters of penetration of dyestuff in mass of matrix and others. Substrate physicochemical behaviour can influence the sample preparation method prior to analysis and extraction efficiency. Preparatory treatment may modify dyestuff component proportions.

By diminishing sample size, the analytical information about dyestuff composition is progressively lost, starting with 'disappearance' from chromatograms of trace substances and continuing through the vague appearance of minor components until the identification of principal compounds is finally uncertain. As a result source recognition precision declines and becomes more difficult to perform. Still, this effect does not affect the relative quantity of dyestuff components. The lower limit of detection depends on performances of the chromatographic system and detector used.

Another modifying factor, dyestuff preparation, affects many stages, from raw material extraction to deposition on substrate. For each step, a multitude of recipes were invented using diverse plant parts and

Figure 5 Some reference samples dyed with European plant extracts containing both luteolin (1) and apigenin (2) (detection at 345 nm). (A) Saw-wort (*Serratula tinctoria* L.); (B) Dyer's Broom (*Genista tinctoria* L.); (C) Weld (*Reseda luteola* L.); (D) *Daphne gnidium* L.

(C)

(D)

Figure 5 *Continued*

varying operation procedures, as well as the addition of different organic and mineral substances to the dyestuffs extracts and dyebaths (Figure 6). Lack of

recent systematic study of the influence of different operations and additives on dye composition restricts interpretation.

Figure 6 Four contemporary reference samples of wool dyed with Madder (*Rubia tinctorium* L.) obtained from different dyers (detection at 254 nm). Compounds: 1 pseudopurpurin, 2 alizarin, 3 xanthopurpurin, 4 purpurin, 5 unidentified anthraquinone.

A third possible dyestuff composition change determinant, which is very important in historical samples, is ageing (Figure 7). The generic name ‘ageing’ en-

folds the conjugated impacts of many physical and chemical factors. Light is considered as the most important of them in dyestuffs degradation. In

**Figure 6** *Continued*

comparison with other colouring matter (e.g. mineral pigments), the stability of dyes' molecular structures under visible light, and especially ultraviolet excita-

tion is poor. Other important factors are water (even as air humidity), air constituents (e.g. ozone), air pollutants (above all sulfur and nitrogen oxides) and,

Figure 7 Accelerated ageing of dyestuff extracted from Brazil (*Caesalpinia sappan* L.) (detection at 285 nm) (A) Freshly dyed wool; (B) Sample after standardized accelerated ageing. Compound 1: brazilein derivative formed during acid hydrolysis.

for archaeological excavated objects, mineral salts solutions giving dangerous pH values. Each of the ageing elements presented represents just a part of the

global process. Determination of their particular roles is possible but does not allow exact modelling or reproduction because of probable synergy between

them. In any case, the methods of 'artificial' ageing (also called 'accelerated' ageing) give a good approximation, sufficient for comparative colour fastness testing.

For textile fabrics it is important to mention the influence of washing and solvent cleaning on the presence of dyestuffs. Their resistance to wet cleaning methods (wash-fastness) is principally related to the dyeing group and washing conditions. Some dyestuffs or their components are sensitive to washing. Such textile handling also belongs to 'ageing', but the adjective 'natural' is in this case probably less adequate.

During ageing two effects are generally observed: hue change and fading. Change of hue is a result of partial dyestuff fading, because of different degradation rates of dye components. Chromatograms obtained from such samples show qualitative and quantitative differences from the original dyestuff. Real sample composition can be ambiguous and similar to several sources, especially if the markers are absent: *in extremis* it can be so far from any known reference that the question of a 'new', not yet identified source can appear. This kind of hypothesis always merits scrupulous verification.

Fading usually signifies transformation of coloured compounds into colourless products. Recent developments in HPLC-MS provides a way to identify original dyestuffs in discoloured samples from their degradation products, even in small amounts. This approach corresponds to expectations of specialists in various domains and will certainly be developed in the future.

Conclusion

In spite of many historic and recent scientific works concerning the chemistry and analysis of natural dyestuffs, our knowledge of this subject still seems to be far from exhaustive. The contribution of HPLC in advances of chemotaxonomy of dyestuffs of plant and animal origin has attracted growing interest in recent years. This technique is relatively easy to perform and does not need any complex sample preparation. Its performances are sufficient for good separation of many dyestuff components in a reasonable time. The HPLC technique provides the possibility of both qualitative and quantitative analysis of separated compounds by employing detectors considered as standard in liquid chromatography (UV, UV-Vis, PDA) or recently adapted, powerful techniques of detection (MSD).

Problems still remaining are directly linked to the biosynthesis of natural dyes (possible pathway vari-

ation) and to their properties (stability, transformation and degradation). They are the principal phenomena affecting chromatogram interpretation. Many of the compounds separated have not yet been identified. Their identification will thus certainly be the objective of future works.

Thin-Layer (Planar) Chromatography

P. E. Wall, Merck Limited, Poole, Dorset, UK

Copyright © 2000 Academic Press

Introduction

Synthetic dyes comprise a large group of organic, organic salt and organometallic compounds which number in the thousands. Most individual dyes are assigned colour index (CI) numbers which helps to identify structure and properties as well as identity where a series of names have been used by the manufacturers for the same dye. Pigments are also listed and can be either organic or inorganic in nature. The value of planar chromatography in the identification of dyes and separation of impurities and their quantification is the main subject of this article. Synthetic dyes will be split into nine groups, the first three being the major ones. For all these groups, the development of modern thin-layer chromatographic (TLC) methods will be compared where possible with older TLC procedures.

Use of TLC for the Separation of Dyes

Synthetic dyes and pigments are used in a wide range of industries. They are the colours of printing inks, textile dyes, cosmetics, plastics, histological and cytological stains, and some are permitted as food and drink colorants. In some of these applications purity is important, in others it is the presence or absence of certain impurities or intermediates, and in still others it is the identification and uniformity that is important. In all these instances planar chromatography has proved to be the ideal solution with the separation power and spot/zone capacity necessary to resolve closely related dyes and intermediates. This has been made possible by the wide selection of stationary phases and the almost unlimited variations possible with mobile-phase mixtures, sometimes composed of quite aggressive solvents that would not be used in column liquid chromatography. The only limiting criteria for the solvent mixtures are adverse effects on the adsorbent binder, reaction with the bonded phases and high viscosity and surface tension of the solvents.

There are a number of other advantages to the use of TLC for the analysis of dyes compared with other chromatographic techniques. The most obvious is

that dyes are easily visualized on a chromatographic layer by their colour. Often slight differences in hue are more clearly seen on the layer than in solution and hence are easily distinguishable. It is therefore rarely necessary to employ detection reagents unless the area of interest is dye intermediates which may lack the conjugation needed in their molecular structure to be coloured in visible light. Of course, there are a large number of dyes which either exhibit fluorescence quenching in short wavelength ultraviolet (UV) light (254 nm) or naturally fluoresce by excitation in long wavelength UV light (usually 366 nm). Where separated dyes on the chromatographic layer do fluoresce, the limit of sensitivity of detection is often in the low nanogram or high picogram level. In the commercial environment, as dye quality can vary from batch to batch and colour can be matched by using different dyes, the planar chromatographic technique allows the analysis of many samples against references or certified standards on the same layer under the same conditions in one development run. Hence the analysis time and the cost per sample are substantially lower when compared with liquid chromatography.

In most forms of chromatography, as in many spectroscopic analyses, the extraction of the dye from whatever matrix is being considered and the subsequent sample pretreatment are often time-consuming, but usually necessary as impure dyes notoriously contain many impurities that are easily and firmly retained on the chromatographic adsorbents. Liquid chromatographic columns and pre-columns quickly become 'poisoned' and then either have to be discarded or require extensive solvent clean-up before re-use. In TLC only minimal clean-up or extraction is required as most polar impurities will remain at or near the origin of application and more nonpolar ones will migrate with the solvent front (normal-phase separation). As the thin-layer plate is not re-used, the unseparated material at the origin or at the solvent front is of no consequence. However, the chromatograms obtained are a source of extensive data about the dye separation. Not only can the chromatographic tracks be scanned spectrodensitometrically, but individual UV/visible spectra of the separated chromatographic zones can be recorded, and a number of other spectroscopic techniques such as mass spectrometry (MS), nuclear magnetic resonance (NMR), Fourier transform infrared (FTIR) and Raman spectra can be applied.

For use in histology, many reference standards are available, as tested and approved by the Biological Stains Commission. Such dyes and stains are labelled accordingly, usually giving the dye content for the batch as numbered. Most such dyes are single components, but where it is known to be composed of two or more components (e.g. methylene violet (3)), azure A or C (up to 6), methyl violet (4), aniline blue (3) and fast green FCF (3)), the dye content will be based on the named dye (usually the major component). The testing of dyes suitable for histology and cytology has always relied on a number of wet chemistry tests, UV/visible spectral analysis, TLC analysis and the actual performance as a stain. The wet chemistry tests include titanous chloride assay, sulfated ash and moisture content. The total dye content has been determined by titration with standard titanous chloride solution and measurement of absorbance (UV). High performance TLC (HPTLC) not only can be used to determine accurately the total dye content, but also the concentration of the individual components if, as so often happens, the sample is either a mixture of dyes or there are impurities present that are closely related structurally to the parent dye (e.g. determination of crystal violet (hexamethyl-pararosanilin) in methyl violet 2B, 3B, 6B or 10B (a mixture of various proportions of hexamethyl-, pentamethyl-, tetramethyl-, and trimethyl-pararosanilin)).

In most industrial uses of dyes (textiles, printing and plastics) and in forensic work, TLC is used for identification and on some occasions to quantify these results. In the commercial environment textile dyes are not normally marketed in the pure state. Both the end user and the manufacturer of the dyes are mainly interested in a dye of standard reproducible quality in their application rather than chemical purity. For this reason the TLC analysis of the dyes for textile, cosmetic or printing purposes presents different problems to that for staining purposes in histology. A commercial dye will often contain impurities composed of by-products of the dye synthesis and starting materials. Inorganic salts are usually present: these have been used to 'salt out' or precipitate the dye during manufacture or they may have been added as extenders, so that different batches have the same dyeing potential. Variations in colour hue are sometimes adjusted by the addition of another dye.

In histology and cytology, although the identity of the dye is important, the purity plays an important part. It has also been realized that other dye impurities need to be present to give a superior quality stain. Both Giemsa and Leishman's stain are classic examples of this. In food and drinks, TLC of dyes can

Table 1 Individual permitted food dyes (depending on country)

<i>Permitted dye</i>	<i>E number</i>	<i>CI number</i>

Yellow 2G (food yellow 5)	E107	

also be a useful technique, as only a limited number of dyes are permitted for food use (Tables 1–4). These are indicated on the label of the food or drink product and can easily be identified by TLC. The presence and identification of nonpermitted food dyes is one of the strengths of TLC.

Many of the early planar chromatography methods for dye analysis in the 1960s used paper or cellulose thin layers. Later, more methods, some still currently used, were based on silica gel G and aluminium oxide thin layers. In more recent times, commercially available pre-coated silica gel and cellulose layers with better reproducibility have become the preferred adsorbents for dye separations. This has become particularly the case where quantitative determinations are required for dye content on HPTLC plates.

f, Faint zone; m, main zone.

For the purposes of planar chromatography, separations of synthetic dyes can be split into a number of groups depending on the ionic nature and molecular structure of the dye. These are:

1. Solvent (fat) dyes.
2. Basic dyes.
3. Acid dyes.
4. Reactive dyes.
5. Disperse dyes.
6. Metal complex dyes.
7. Direct dyes.
8. Organic pigments.
9. Food colorants.

As mixtures of dyes generally fall into these respective groups and it is rare, if ever, that a dye from one of the major structural groups is found mixed with another, the TLC will be examined in detail for each group in turn. This is important as the polarity

of solvents employed for the TLC separations of dyes within each group is similar and notably different from those used for other groups.

Solvent (Fat) Dyes

As their name suggests, solvent dyes are dyes soluble in nonpolar solvents (mostly water-immiscible), and are used to colour mineral oils, waxes, fats and plastics. They are lipophilic in nature and do not form organic salts. Structurally the dyes are characterized by the azo, quinone-imine (indophenol dyes), or anthraquinone (waxoline dyes) groups they contain. By far the largest group is the azo dyes. These are mainly monoazo (sudan dyes) and a few disazo dyes (e.g. Sudan red B (CI 26110), oil red O (CI 26125; Figure 1).

Although TLC separations of solvent dyes have been reported on alumina layers, silica gel is by far the preferred adsorbent. Separation of solvent dyes

**Figure 1** Solvent dyes. Structures of characteristic groups.

Table 4 R_F values for Sudan III and IV on silica gel 60 RP8 HPTLC pre-coated plates. Plate developed in a saturated chamber

Solvent dye	R_F value	Developing solvent
Sudan III	0.32	Methanol-acetic acid-water
Sudan IV	0.22	(90 + 5 + 5 v/v)

on standardized silica gel G layers was reported in the early 1960s by Stahl. This was one of the first recorded separations on silica gel and described the resolution of butter yellow (CI 11020), Sudan R (CI 12150) and indophenol (CI 49700) using a mobile phase of pure benzene. In the years that followed, a variety of similar-polarity solvents were reported as suitable with silica gel G. Chloroform and benzene and mixtures of petroleum spirits, and single aliphatic hydrocarbons with ethyl acetate, diethyl ether, acetone and methanol were used to separate butter yellow, Sudan orange R (CI 12055), Sudan III (CI 26100) and Sudan red BB (CI 26105). The anthraquinone series of dyes have been separated with toluene-cyclohexane (50 + 50% v/v) on silica gel G. This readily resolves solvent blue 36, waxoline purple A (CI 60725) and waxoline green G (CI 61565). Dimethylaminoazobenzene and related dyes are separated using the solvent chloroform-methanol (95 + 5% v/v) on the same stationary phase.

Most solvent dyes will readily migrate and separate from each other on commercially pre-coated silica gel 60 TLC layers using the same or similar polarity

solvents to those used on silica gel G. However, the separated chromatographic zones on pre-coated plates are much sharper, noticeably less diffuse and misshapen, leading to good overall resolution (Figures 2 and 3). This should be expected as the silica gel will have a much narrower particle size distribution over the particle size range, and a mean particle size (10–12 μm) less than that of a 'home-made' plate.

The resolution can be further improved for Sudan dyes by using a reversed-phase adsorbent. In fact, the resolution is so good that results can be quantified on an HPTLC silica gel 60 RP8 plate (Merck) by scanning the developed plate at 540 nm (Figure 4). In this example, samples were applied as spots of 100 nL with a manual nanoapplicator (CAMAG). The relative standard deviation was 4.5%.

**Figure 2** Separation of two main components of Sudan black B on silica gel 60 pre-coated TLC plates. Developed in a saturated tank with dichloromethane as solvent. Scanned with a spectrodensitometer at 540 nm.**Figure 3** Separation of fat red 7B from one main impurity on silica gel 60 pre-coated TLC plates.

Basic Dyes

Basic dyes form one of the larger areas of interest when it comes to TLC. As their name suggests, they are bases which can form salts which are soluble in water. Their applications vary widely in industry, including colouring paper, some textiles and plastics, and are used as the basis of many biological stains.

Basic dyes include the following structural groups: triarylmethanes (mostly triphenylmethanes), quinon-eimines, azo, acridine and xanthene compounds (**Figure 5**). These can be further split: the triarylmethanes into amino and hydroxy derivatives and the quinone-imines into indamins, azins, thiazins and oxazines. **Table 5** shows some of the commonly named dyes which fit into these groups.

As with solvent dyes, much of the early separation work was performed on silica gel G. **Table 6** lists a number of solvent mixtures which have proved useful in the separation of the general classes of basic dyes. With the advent of commercial TLC and HPTLC pre-coated silica gel 60 and bonded phases, the separation methods have improved, allowing resolution of dyes with closely related structures, and the determination of concentrations of individual dyes by *in situ* scanning using a spectrodensitometer (**Table 7**). Hence thiazin dyes are now easily resolved, including

Figure 5 Acid and basic dyes. Structures of characteristic groups.

Table 5 Commonly named basic dyes according to their structural groups

Basic dye groups	Commonly named dyes
Triaminotriarylmethane	Pararosanilin New fuchsin Rosanilin
Diaminotriarylmethane	Malachite green Brilliant green Victoria blue

Methylene blue, malachite green	Ethyl acetate-acetic acid-water (30 + 10 + 20 v/v)
Crystal violet, methylene blue, malachite green, basic fuchsin	Butan-1-ol-acetic acid-water (20 + 5 + 10 v/v)

thionine, azure A, B, C and methylene blue on HPTLC silica gel 60 using a mobile phase of butan-1-ol-butanone-acetic acid-water (30 + 20 + 10 + 10 v/v). Methylene blue can easily be distinguished from new methylene blue even though their visible/UV spectra are almost identical (Figure 6).

Many of these dyes are the basis of the biological Romanowski stains (Giemsa, Leishman, Wright, Jenner and May-Grunwald). An assessment of the dye quality of the stain and its individual dye components can be made by the above chromatographic methods. Usually the 'ripened' or oxidized versions of these stains produce the better histological staining properties. Oxidation produces more azures and thionine, all of which can be determined, if required, by HPTLC procedures. The complete resolution of methylene blue and its oxidation products including azures and thionine presents a difficult problem even for HPTLC as these dyes are all closely structurally related. A typical example of such a separation is

shown in Figure 7 (separation of the blue dye components of Wright's stain) on a normal-phase pre-coated silica gel 60 plate (Merck).

For most basic dyes, TLC and HPTLC silica gel 60 layers normally give sufficient resolution and have proved in some cases to be suitable even for the separation of dyes from closely related impurities (Figure 8). In special cases, either reversed-phase layers or other bonded layers have solved particularly difficult separation problems. One of these has been the separation of pararosanilin from rosanilin, new fuchsin and magenta II. Pure pararosanilin is used in the preparation of Feulgen and Schiff's reagent for aldehyde and ketone detection and in biological staining. All four compounds are triaminotriphenylmethane dyes, differing consecutively by one methyl group. Although silica gel 60 RP8 HPTLC layers are able to resolve just the four components, tailing problems make it difficult to scan the zones quantitatively. However, by introducing the ion-pairing reagent

Table 7 Solvent systems for individual basic dyes on silica gel 60 TLC and HPTLC pre-coated plates. R_F values obtained and recommended scanning wavelength for detection

m, Main zone.

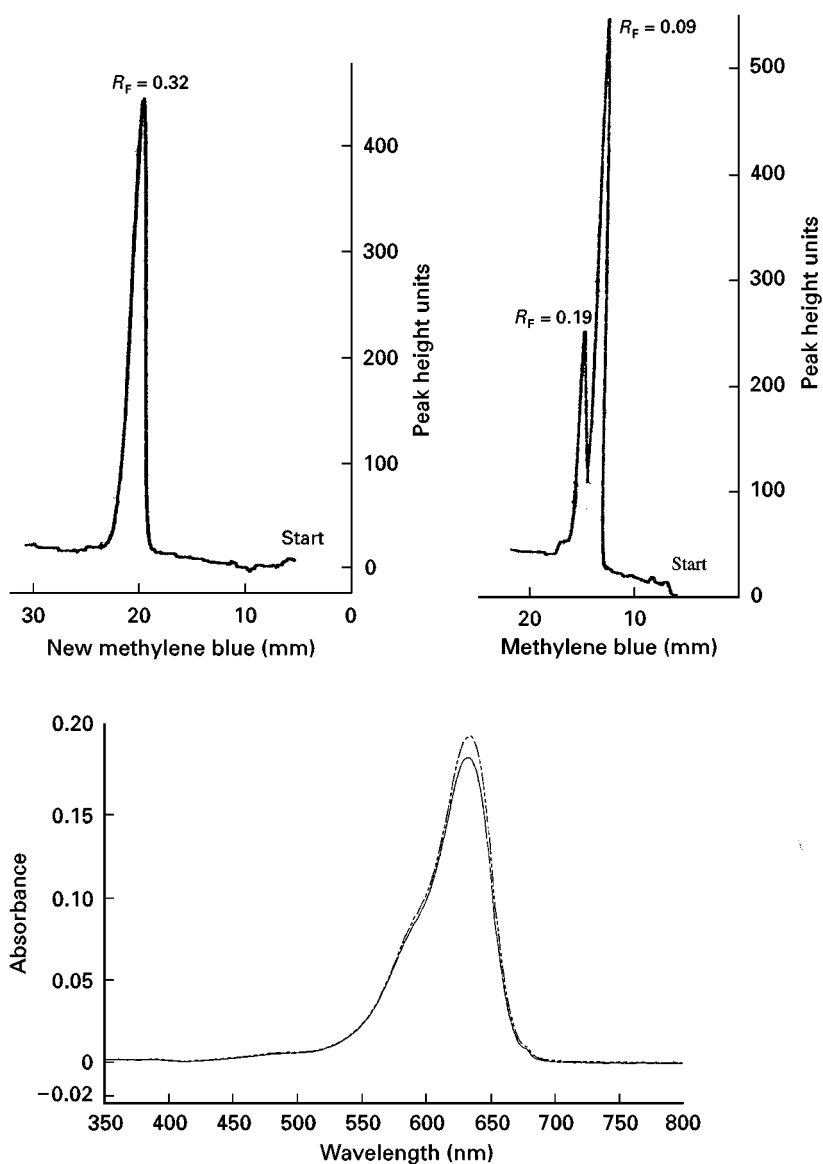

Figure 6 Comparison of methylene blue separation with new methylene blue. Both separated on silica gel 60 pre-coated TLC plates with butan-1-ol–acetic acid–water (50 + 5 + 10 v/v) as mobile phase. Overlaid spectra also shown.

pentanesulfonic acid sodium salt (2%) into the developing solvent mixture (methanol–water–formic acid: 75 + 20 + 5 v/v), the effect of tailing is dramatically reduced, allowing quantitative determination of all four dyes. Another difficult separation problem arises with Bismarck brown Y and R. Resolving the dyes from their impurities is not easily achieved. In this instance silica gel 60 NH_2 -bonded HPTLC layers have proved successful (Figure 9).

Acid Dyes

Like basic dyes, acid dyes are used widely throughout industry. They are the basis of inks and biological

stains and are used for colouring wool, polymer fibres, leather and paper. They are mostly sulfonic and carboxylic acid compounds, often prepared as their sodium salts to enable good water solubility. They can be split into a range of structural groups: azo, triarylmethane, xanthene, anthraquinone and quinone-imine. The separation of these groups on silica gel G and cellulose using a variety of solvent mixtures for development is given in a number of the older TLC books found in the Further Reading list.

Commercial pre-coated silica gel 60 TLC and HPTLC plates, where the adsorbent has a carefully controlled pore size and particle size, give improved resolution of acid dyes compared with that obtained

Figure 7 Separation of blue components of Wright's stain. Stationary phase is silica gel 60 pre-coated TLC plate. Mobile phase is ethyl acetate-methanol-ammonia solution (0.88)-water (35 + 11 + 5 + 5 v/v). Mixture of methylene blue, azures A, B and C, and thionine and other oxidation products.

for example with silica gel G. It has been possible to quantify results by spectrodensitometric scanning in a comparable way to basic dyes (**Figure 10**). Purity can be determined with a high degree of accuracy as is shown with the commercial samples of light green (**Figure 11**). Typically, five standards of certified dye are developed on the same plate alongside the samples. Peak measurements are made by reflectance and an x-power curve plotted against concentration. Unknowns are determined with about $\pm 1\%$ standard

Figure 8 Separation of crystal violet from other closely related less methylated pararosanilins. Stationary phase: silica gel 60 pre-coated HPTLC plates. Mobile phase: butan-1-ol-acetic acid-water (50 + 5 + 10 v/v). Peak 1: hexamethylpararosanilin (crystal violet), peak 2: pentamethylpararosanilin.

deviation. It is also possible to determine where rogue dyes have been used to try and replace the genuine dye. Examples of Congo red and brilliant cresyl blue are shown in **Plates 1** and **2**.

More recently, reversed-phase silica gel layers have proved useful for acid dyes where separation has not been possible on normal-phase silica gel. An example of this is eosin bluish shade, where reversed-phase plates have proved satisfactory, as shown in **Table 8**.

Reactive Dyes

Reactive dyes attach themselves to cellulose fibres in wool and cotton. They are structurally defined into the groups azo, anthraquinone and phthalocyanine derivatives. One well-known commercial group is the procion dyes which can be separated on silica gel G with solvent mixtures – butan-1-ol-propan-1-ol-ethyl acetate-water (20 + 40 + 10 + 30 v/v) and dioxane-acetone (50 + 50 v/v).

Hydrolysis products of reactive dyes have also been examined by TLC on silica gel using the solvent mixture butan-1-ol-pyridine-water-ammonia (0.88 solution: 15 + 5 + 3 + 2 v/v), and with solvent mixture chloroform-methanol-acetone (18 + 3 + 2 v/v) with detection at 310 and 614 nm using a spectrodensitometer. The TLC of the reaction product and hydrolytic by-products of terminal ring isomers of reactive blue 2 (an anthraquinone dye) have been studied on silica gel using butan-1-ol-propan-2-ol-ethyl acetate-water (20 + 40 + 10 + 30) as developing solvent.

Disperse Dyes

Similar in structure to fat-soluble dyes, disperse dyes are mainly used to colour cellulose acetate and polymer fibres (principally polyester). They exhibit low solubility in water, but are soluble in organic solvents. Disperse dyes are types of nitrodiphenylamine, azo and anthraquinone dyes, but not those associated with either sulfonic or carboxylic acid groups. Commercially they belong to the Celliton group of dyes which can be separated by TLC on silica gel G adsorbent using chloroform-methanol (95 + 5 v/v) as mobile phase. Better separations of amino derivatives of anthraquinones have been obtained using chloroform-acetone (90 + 10 v/v). Mixtures of chloroform-ethyl acetate (50 + 50 v/v) or various dilutions of toluene with acetone can be employed on pre-coated silica gel 60 layers. When analysis of the dyes is required in natural and synthetic polymers, dichloromethane, acetone or dimethylformamide can be used to extract them ready for application to the TLC plate.

Figure 9 Separation of Bismarck brown Y and R on silica gel 60 NH_2 pre-coated HPTLC plates. Mobile phase: industrial methylated spirit. (A) The two components of Bismarck brown Y; (B) Bismarck brown R.

Metal Complex Dyes

These are acid dyes, mostly belonging to the azo group. They can be divided into two distinct types: 1 : 1 and 1 : 2 complexes.

1 : 1 Complexes

These are water-soluble dyes of sulfonic acid type which can be separated by TLC on silica gel using the solvent systems described under the section on acid dyes. For the most part they are chromium complex dyes.

1 : 2 Complexes

These are water-insoluble, but solvent-soluble dyes. They are metal complexes of chromium and cobalt. The best adsorbent for separation on thin layers is polyamide using a solvent mixture of methanol–water–ammonia (0.88 solution: 80 + 16 + 4 v/v).

Direct Dyes

Direct dyes are used for dyeing cotton fibres and leather. They are mainly polyazo dyes which can be

Figure 10 Quantification of Congo red dye. Single component dye. Typical x-power fit for reflectance data against concentration for a batch of certified dye. Stationary phase: silica gel 60 pre-coated HPTLC plates. Mobile phase: ethyl acetate–methanol–ammonia solution (0.88)–water (35 + 11 + 5 + 5 v/v).

well separated on silica gel layers. Some, like Congo red, Evan's blue and trypan blue, have already been discussed under the acid dye section, but others can be resolved using the same solvent mixtures as recommended for the above dyes in Table 9. Slight modifications to the ratio of the solvents can often further optimize the solvent mixture for the specific dye.

Figure 12 (See Colour Plate 78). Set of certified Congo red standards developed on a silica gel 60 HPTLC layer. Mobile phase: ethyl acetate-methanol-ammonia solution (0.88)-water (35 + 11 + 5 + 5 v/v). A minor impurity is visible at R_f value 0.07. The two dye substances alongside these are of a dye that was claimed to be Congo red.

Organic Pigments

These are the colours of artist's paints which are also used for pigmenting rubbers and plastics. Included

Figure 13 (See Colour Plate 79). Separation of brilliant cresyl blue on silica gel 60 HPTLC plate. Mobile phase: ethyl acetate-methanol-ammonia solution (0.88)-water (35 + 11 + 5 + 5 v/v), saturated tank. Six standards applied at increasing concentration (from 50 ng) on the right side of the plate. The six samples developed on the left, all of equal concentration, were claimed to be brilliant cresyl blue, but in fact were a mixture of toluidine blue and Nile blue sulfate.

Table 8 Commonly named acid dyes according to their structural groups

<i>Acid dye groups</i>	<i>Commonly named dyes</i>	<i>Colour index numbers</i>

	Azocarmine B	50090
Anthraquinone	Alizarin red S	58005
	Indigo carmine	73015

here are the phthalocyanine dyes along with some azo, vat and anthraquinone dyes. They are for the most part insoluble in both organic solvents and water. Hence chromatographic separations have proved difficult. However, some chromatographic work has been described. Some pigments will dissolve in hot dimethylformamide. They can then be applied as such to silica gel layers. Thorough drying is recommended before development with benzene or benzene modified with chloroform. The use of paper chromatography has also been described with propan-1-ol-ammonia (0.88 solution: 20 + 10 v/v) as mobile phase.

Food Colorants

Acid dyes are used as colorants in food and drink. In the past, the recommended stationary phase for food dye separations was either cellulose or modified celluloses (diethylaminoethyl (DEAE), PAB). However, as in other areas of modern TLC, silica gel 60 has taken over as the preferred stationary phase. The optimum chromatographic conditions have therefore to a large extent already been described in the acid dye section. However, for completeness the optimum resolution

of many of these dyes is listed in Table 10. These dyes are all water-soluble and separate readily on thin layers of silica gel 60. As they are ionic in nature, it is important that either acid or base modifiers are used in the solvent mixture (e.g. acetic or formic acids or ammonia solution). This reduces 'tailing' or 'streaking' of chromatographic zones by either suppressing ionization or totally ionizing the components of the sample.

Commercial dyes for food use are often blends of permitted acid dyes, e.g. green food dye is usually a mixture of brilliant blue FCF (E133) and tartrazine (E102); red food dye can be a mixture of red 2G (E128) and tartrazine (E102). The TLC methods must therefore have the ability not only to separate impurities, but also to resolve the parent dyes.

Most food dyes are prepared for use in a glycerine base. Although little pre-chromatographic preparation of samples is required, it is important where this base is used to solubilize these dyes further with water-methanol (50 : 50 v/v) so that when the sample is applied to the plate, the sample solution will properly 'wet' the layer. Solutions can be filtered if required. As the dyes are so readily soluble in water, their extraction from the food matrix does not usually present a problem. For colours in drink, the sample normally only requires dilution with methanol before application as a spot or band to the chromatographic layer.

Future prospects

Future prospects of dye analysis using TLC/HPTLC are likely to be closely linked with the use of video imaging techniques (charged coupled devices). Usually dye analysis involves many samples in a commercial environment. Hence a technique that has the ability to take a video image of an entire developed plate which could contain many chromatograms, and has the software capabilities to determine concentrations with some degree of accuracy from the image density of the chromatographic zones, has a real benefit to the analyst. Hard-copy pictures of the chromatograms can be produced for entry into analytical reports. The speed of such analysis will undoubtedly improve as the speed of computation becomes ever faster and further software improvements are made.

The identification and possible quantification of minor dye impurities will also become more feasible as hyphenated techniques such as FTIR, MS and Raman spectroscopy are linked to HPTLC and become more widely used. Manufacturers of pre-coated plates are now commercially producing smaller particle size adsorbents (3–5 µm), some based on spheri-

cal shaped particles. These will have the advantage of better flow characteristics for the migrating solvent, although slower flow rates and, most importantly for dye impurity analysis, improvement in sensitivity. The smaller average particle size and spherical shape will mean that such minor components on the layer

will be more concentrated with less diffusion than that presently seen on an HPTLC plate.

Introduction

Ecdysteroids are present both in animals (mainly Arthropods) and plants and comprise about 300 different molecules related to ecdysone (**Figure 1**). Structural variation in the number of carbons on the side-chain and of substituents at various positions (**Table 1**) results in the presence of compounds displaying very different polarities. Most available chromatographic techniques have been applied to the isolation and analysis of ecdysteroids. Paper chromatography is now obsolete and no longer used. Gas chromatography (GC) is of limited use, as the derivatization procedures necessary to make volatile derivatives require careful control. Currently, the most widely used techniques are high performance liquid chromatography (HPLC) and thin-layer chromatography (TLC), with the former providing the major analytical methods.

Liquid-Liquid Partitions

The simplest separation method concerns partitioning between two non-miscible solvents, and it is currently used for clean-up of biological samples. On this basis, several procedures have been designed, which allow the preparation of almost pure compounds in the gram scale.

Solvent Partitioning

Partition between n-butanol and water can be used to remove polar contaminants, whereas partition between aqueous methanol and hexane removes non-polar materials. Lipids can also be removed from aqueous extracts with hexane-methanol (7 : 3, v/v), light petroleum or n-propanol-hexane (3 : 1, v/v). The nature of the contaminants to be removed and that of the ecdysteroids to be isolated govern the choice for a given partition system. The number of free -OH groups significantly affects partition coefficients (**Table 2**).

The combination of two successive partition steps allows the elimination of both polar and apolar contaminants. It is thus possible to combine (1) chloroform/water and (2) water/butanol. This results in a butanol-containing fraction that is significantly enriched. It is possible to select a narrower range of polarity by replacing chloroform with a more polar organic solvent, e.g. isobutyl acetate, that nevertheless allows ecdysteroids to remain in the water phase.

Figure 1 The structure of ecdysone, the first ecdysteroid isolated from *Bombyx mori* pupae.

Table 1 Variations on the 20-hydroxyecdysone molecule

Type	Positions on the molecule
Hydroxyl groups	
Additional -OH	1, 5, 11, 16, 18, 19, 23, 24, 26
Missing -OH	2, 20, 22, 25
Oxidation	
(>CHOH → >C = O)	3, 22
(-CH ₂ OH → -COOH)	26
(→ epoxide)	22-23
Epimerization	3 α /3 β , 5 α /5 β
Alkyl substitution	24 (methyl, methylene, ethyl, etc.)
Esterification	
Acetates	2, 3, 22, 25
Fatty acyls	22
Benzoates	20, 22, 25
Cinnamates	2
Coumarates	3
Phosphates	2, 22, 26
Sulfates	22
Lactone ring formation	Concerns mainly C-28 or C-29 ecdysteroids
Etherification	
Intramolecular	Between C-22 and C-25
Methoxy ether	25
Ketal/acetal formation	
Acetonides	2-3, 20-22
Benzylidene acetals	20-22
Glycosylation	
Galactosides	3, 22
Glucosides	3, 22, 25, 26
Dehydration	9(11), 14(15), 24(25), 25(26)
Side-chain cleavage	C-20/C-22, C-17/C-20

Counter-current Distribution

Counter-current distribution (CCD) is a multi-tube extension of the above partition procedure. Butenandt and Karlson (1954) purified the first ecdysteroid (ecdysone) from *Bombyx* pupae by CCD with butanol-cyclohexane-water (4 : 6 : 1). This technique is presently of limited use, and it has been replaced by the more convenient droplet counter-current chromatography technique described below.

Droplet Counter-current Chromatography

Droplet counter-current chromatography (DCCC) allows an efficient purification of crude samples up to the gram range (Table 3). DCCC enables the preparation of reasonably, although not absolutely, pure compounds (a subsequent HPLC step may be required to get pure ecdysteroids). One DCCC separation usually lasts several days: exchanges between

Table 2 Partition coefficients (*K*) of ecdysteroids (data from Lafont *et al.*, 1994b)

Ecdysteroid	<i>K</i>

2,22-Dideoxyecdysone	13.0
2-Deoxyecdysone	2.7
Ecdysone	0.4
20-Hydroxyecdysone	0.1

$$K = \frac{\text{concentration in the non-polar phase}}{\text{concentration in the polar phase}}$$

mobile droplets and the stationary phase is the rate-limiting process. High-speed counter-current chromatography (HSCCC) overcomes this drawback and separations are performed within a few hours. This technique has so far only been applied to the ecdysteroids in a small number of cases.

Thin-Layer Chromatography (TLC)

Normal-phase (absorption) chromatography on silica gel has been used extensively in the isolation of ecdysteroids and for metabolic work. Despite the advent of HPLC, the low expense, simplicity and speed of TLC ensures a continuing role for this technique in ecdysone research.

Chromatographic Procedures

Normal-phase systems Many solvent systems have been used for TLC of ecdysone and related compounds, and these are summarized in Table 4. A wide range of *R_F* values on silica gel have been reported.

Table 3 Solvent systems for droplet counter-current chromatography (DCCC)

Solvent system	Mode
CHCl ₃ /MeOH/H ₂ O (13 : 7 : 4)	Ascending
CHCl ₃ /C ₆ H ₆ /EtOAc/MeOH/H ₂ O (45 : 2 : 3 : 60 : 40)	Descending
C ₆ H ₆ /CHCl ₃ /MeOH/H ₂ O (5 : 5 : 7 : 2)	Descending
CHCl ₃ /MeOH/H ₂ O (65 : 20 : 20)	Descending

CHCl₃, chloroform; MeOH, methanol; C₆H₆, benzene; EtOAc, ethyl acetate.

Table 4 Some representative solvent systems for TLC of ecdysteroids on silica gel

Solvent system	Composition	$[R_F]$	
		E	20E
CHCl ₃ /95% EtOH	7 : 3	0.39	0.34
CHCl ₃ /MeOH	9 : 1	0.10	0.07

For consistent results, plates should be heated at 120°C for 1 hr, then deactivated to constant activity over saturated saline. An example of the type of separation that can be achieved in metabolic studies in insects is shown in Figure 2.

Reversed-phase systems An alternative to normal-phase TLC (NP-TLC) is reversed-phase TLC (RP-TLC) on silica bound to alkyl chains (2 to 18 carbons). Methanol-water, ethanol-water, isopropanol-water, acetonitrile-water and acetone-water systems have been used as mobile phases, with methanol-water solvents providing the most general solvent system. The order of migration in RP-TLC is roughly opposite of that seen using NP-TLC (Table 5). Results vary significantly with plate manufacturers. Changing the proportion of methanol in the sol-

Detection of Ecdysteroids after TLC

Detection of ecdysteroids on the TLC plate can be accomplished using a set of techniques of varying specificities (Table 6). Non-specific techniques include iodine vapour, heating in the presence of ammonium carbonate (which produces fluorescent spots), or fluorescence quenching if a fluorescing agent is incorporated into the silica. More specific reagents such as the vanillin-sulfuric acid spray can be used to give spots of characteristic colour. Sulfuric

acid or ammonia give fluorescent reactions, with the former being slightly more specific.

Evolved TLC Techniques

Automatic multiple development (AMD) In AMD, the plate is repeatedly developed with the same solvent, which migrates more and more with each development. This method allows a reconcentration of ecdysteroids at each run, in particular by suppressing tailing, and this finally results in sharper bands and improved resolution.

Over-pressure layer chromatography (OPLC) In OPLC, the solvent is forced through the layer by an HPLC pump and the plate can be developed within minutes. The use of high-performance TLC plates rather than conventional TLC plates is recommended for optimal results. Developing the plates under these conditions will minimize diffusion, while allowing mass transfer to proceed.

Neither AMD nor OPLC have been used to any significant extent for the separation of ecdysteroids, although where they have been employed for these compounds good results have been obtained.

Low-Pressure Column Chromatography

Preparative Columns

These systems are used for the isolation and purification of ecdysteroids from crude extracts. Columns are

filled with either normal (polar) phases (silica or alumina) eluted with organic solvents, or non-polar phases (Amberlite XAD-2, polyamide or Sephadex LH20) eluted with aqueous mixtures (Table 7). Ion-exchange phases (e.g. DEAE-Sephadex) eluted with buffers can be used for polar anionic ecdysteroids (Figure 4). The size of the column has to be adapted to that of the sample, with a sorbent-to-sample ratio higher than 50 (w : w), and these methods can be used with very large samples. They represent a rather cheap and reasonably efficient procedure for getting fractions from which ecdysteroids can be crystallized (if present in large amounts) or further purified by HPLC (see below). Step-gradient elution with solvents of increasing strength allows the separation of ecdysteroids over a wide range of polarity.

Disposable Cartridges

Small solid phase extraction (SPE) cartridges containing 0.2–1 g of non-polar HPLC phase allow the clean-up of small samples with a good recovery (Figure 5). They can also be used to adsorb ecdysteroids from aqueous media, thus allowing an easy and quantitative recovery of ecdysteroids from organ/cell culture media or from HPLC fractions when a non-

volatile buffer is used. Normal-phase SPE cartridges have also been used for the fractionation of biological extracts.

Figure 4 Separation of acidic ecdysteroids from *Manduca sexta* using a DEAE-Sephadex column (6.5 cm long, 2 cm i.d.). Elution was performed with a step-gradient of NaCl. Peak 2 contains ecdysonic acids, peak 3 contains phosphate conjugates. High Performance Liquid Chromatography

High performance liquid chromatography (HPLC) offers a wide range of techniques for analytical and preparative purposes. Co-migration of a compound with a reference ecdysteroid in one (or several) solvent system(s) represents the usual way for identification of the compound. Some common HPLC systems are listed in Table 8.

Chromatographic Procedures

Ecdysteroid detection

UV detectors are well-suited to the detection of ecdysteroids, as most ecdysteroids possess a conjugated 7-en-6-one moiety which provides a strongly absorbing chromophore (λ_{\max} 242 nm, $\log \epsilon$ ca. 4). This allows the easy detection of less than 10 pmol amounts.

Diode-array detectors provide information about the absorbance spectrum of all eluted peaks. It can thus be directly checked whether a compound co-migrating with a reference ecdysteroid has a suitable UV spectrum. Good spectra can be obtained with very small amounts (less than 100 ng) of ecdysteroids and such data provide an additional criterion to assess the identity of UV-absorbing peaks.

Fluorescence detectors require the preparation of fluorescent derivatives of ecdysteroids, which may increase the sensitivity of detection by two orders of magnitude when compared with UV. Phenanthrene boronic acid, a reagent specific for α -diols (here the 20,22-diol), and 1-anthroyl nitrile, which reacts with alcohols (here the 2-OH of ecdysteroids), have been used. These reactions, however, are not specific enough for ecdysteroids and they have not been widely adopted.

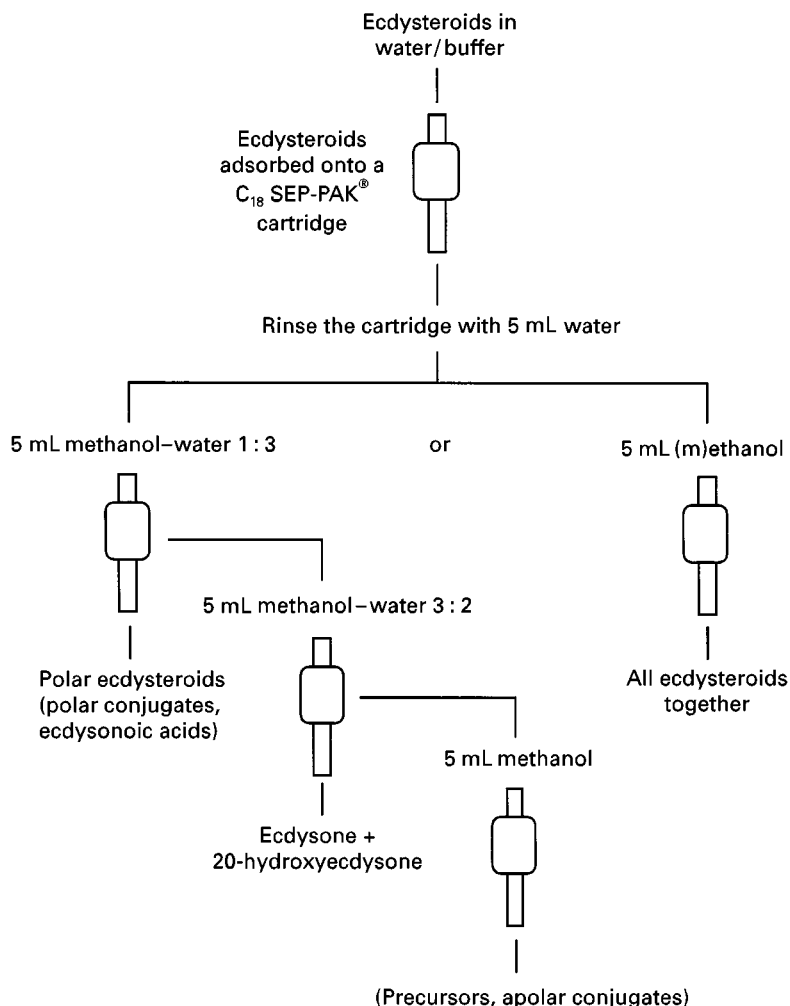

Figure 5 Utilization of reversed-phase cartridges for ecdysteroid purification. The cartridge must be rinsed with 5 mL MeOH then 5 mL water prior to use. Redrawn from Lafont R, Morgan ED and Wilson ID (1994) Chromatographic procedures for phytoecdysteroids. *Journal of Chromatography* 658: 31–53, with permission from Elsevier Science.

Table 8 Chromatographic systems commonly used for the HPLC analysis of ecdysteroids

Mode of chromatography	Polar		Medium	Apolar
	Ionic	Nonionic

Radioactivity monitoring provides a direct comparison with UV absorbance, and this easily allows one to make correspondence between the radioactive peaks and unlabelled reference compounds added in the sample before injection. They are currently used for metabolic studies.

Mass spectrometry (MS) gives important structural information. The interfacing problems between HPLC and MS have been overcome in recent years and this technique will undoubtedly develop in the future. An example of HPLC-MS applied to an ecdysteroid-containing plant extract is given in **Figure 6**.

Nuclear magnetic resonance spectrometry can also be used on-line to identify ecdysteroids. This requires rather expensive deuterated HPLC solvents and the method is only suitable for plant extracts where ecdysteroid concentrations are high enough. An example of the use of this emerging technology in a plant extract is shown in **Figure 7**.

Off-line procedures may be used to improve the sensitivity and/or selectivity of ecdysteroid detection (or to identify ecdysteroids after preparative HPLC purification). These analytical methods include chiefly immunoassays (RIA, EIA) and also several recently designed *in vitro* bioassays.

Normal-phase systems Normal-phase HPLC systems generally use silica columns (sometimes polar-bonded columns) and, for example, dichloromethane-isopropanol-water mixtures. Non-polar ecdysteroids (such as esters or precursors) can be separated with a 125 : 15 : 1 (v/v/v) mixture, medium-polarity compounds (such as ecdysone and 20-hydroxyecdysone) with a 125 : 30 : 2 mixture, and more polar (but non-ionic) ecdysteroids (such as 26-hydroxyecdysteroids and glucosides) with 125 : 40 : 3 or 100 : 40 : 3 mixtures.

Dichloromethane-based solvents strongly absorb UV and do not allow UV spectra to be obtained with diode-array detectors, nor are they well suited to in-line radioactivity monitoring (due to their quenching properties). These problems do not exist with

Figure 6 Reversed-phase HPLC-MS total ion current trace (upper) of an extract of *Silene otites*. Peak 1, integristerone A; 2, 20-hydroxyecdysone; 3, 2-deoxy-20-hydroxyecdysone; 4, 2-deoxyecdysone. The mass spectra (lower) are of 20-hydroxyecdysone (left) and integristerone A (right). Structures in insets to mass spectra. After Wilson ID, Lafont R, Shockcor JP *et al.* (1999) High-performance liquid chromatography coupled to nuclear magnetic resonance spectroscopy and mass spectrometry applied to plant products: Identification of ecdysteroids from *Silene otites*. *Chromatographia* 49: 374–378, reprinted with permission.

cyclohexane-based mixtures, however, the poor solubility of ecdysteroids in these mixtures causes some problems for the analysis of polar ecdysteroids and also for preparative purposes.

Polar-bonded columns (e.g. -diol, -polyol or -aminopropylsilane, APS) can also be used. Diol-bonded columns used with extracts of the phasmid *Carausius morosus* allowed the separation of a wide array of polar and non-polar metabolites, whereas the APS phase has provided efficient separations of mixtures containing 3 α -OH, 3 β -OH and 3-oxo ecdysteroids. One major interest in such polar-bonded columns is that solvent gradients can be used, whereas lengthy re-equilibration times would be the case with silica columns.

Reversed-phase systems Reversed-phase HPLC on C₁₈-bonded columns eluted with methanol–water

mixtures provides the most widely used system. Acetonitrile–water (acetonitrile–buffer) mixtures are more efficient, especially when polar conjugates and/or ecdysonic acids are present. Adequate systems have been designed for polar and apolar metabolites, which may both be present within the same sample. Surprisingly, apolar fatty acyl esters of ecdysteroids are not eluted with pure acetonitrile, whereas they are with methanol, despite the fact it is a more polar solvent (the same is true for cholesterol).

In the case of polar (ionizable) metabolites, it may be of interest to use different pHs, which will result in modified retention times, while uncharged ecdysteroids will retain the same elution time. Moreover, this gives an easy access to the pK_a value of ionizable groups, which is of interest for the characterization of conjugates.

Ion-exchange chromatography Anion-exchange columns are used for the purification of polar conjugates. They represent an efficient method, complementary to reversed-phase HPLC. However, using two different pHs (e.g. pH 7.5, then 2.5) with HPLC, provides an equivalent opportunity for obtaining pure ionizable conjugates, e.g. phosphate esters.

Various Aims of HPLC

Analytical and preparative HPLC Columns of different sizes with the same packing are available, therefore it is very easy to scale up any chromatographic separation. Maximum sample load is related to the amount of stationary phase in the column. In

Figure 7 Stopped-flow HPLC-NMR spectrum of 20-hydroxyecdysone following reversed-phase HPLC on a C₁₈-bonded column with D₂O acetonitrile as mobile phase. (Reproduced with permission from Wilson ID, Morgan ED, Lafont R and Wright B (1998) High-performance liquid chromatography coupled to nuclear magnetic resonance spectroscopy. Applications to the ecdysteroids of *Silene otites*. *Journal of Chromatography A* 799: 333–336).

favourable cases, samples up to the milligram range can be run on analytical columns. Larger amounts, of course, require wide-bore columns. It may happen that some compounds that are baseline resolved when loading is low, are not well separated with a larger load. This is, for instance, observed with the inokosterone/20-hydroxyecdysone pair run on a semi-preparative column (Zorbax®-SIL, 9.6 mm i.d.), even when less than 0.5 mg is injected.

Quantitative analyses HPLC has been used for the direct quantification of individual ecdysteroids in biological samples. For animal extracts, this requires a high sensitivity because of the low concentrations

present and adequate sample clean-up. The most reliable quantification is obtained if an internal standard is added before sample purification. Many phytoecdysteroids can be used as internal standards. The choice must be made after a preliminary run of a representative sample in order to select a compound that does not co-migrate with major impurities and of course differs from the ecdysteroids present in the biological extract.

Selectivity in HPLC

Both isocratic reversed-phase and normal-phase systems can separate rather complex ecdysteroid mixtures, and the use of solvent gradients increases the

Analytical columns were either a Zorbax-Sil column (DuPont), 25 cm \times 4.6 mm i.d., eluted with DIW (dichloromethane-isopropanol-water, 125 : 30 : 2) or CIW (cyclohexane-isopropanol-water, 100 : 40 : 3) or a Spherisorb 5ODS2 (Biochrom), 25 cm \times 4.6 mm i.d., eluted with water + 1% (final concentration) trifluoroacetic acid and either 23% acetonitrile (AW), 50% methanol (MW), or 18% isopropanol (IW). Flow rate was 1 mL min⁻¹ in every case.

power of these systems. In order to draw up general rules, it is necessary to analyse the HPLC behaviour of numerous ecdysteroids differing by single or multiple modifications, and to use a set of different HPLC systems. A set of such data are given in Table 9, and the corresponding conclusions are given in Table 10.

Selectivity in NP-HPLC

Columns NP-HPLC columns are packed with either silica or polar-bonded silica. The use of diol-bonded material instead of silica does not introduce large changes; retention times vary, but the elution order

Table 10 Effects of individual changes (with reference to the 20E molecule) on the chromatographic behaviour of ecdysteroids as analysed using various chromatographic systems

Change	Effect on capacity factor (k')

Changes of the k' value are described as follows: --, strong reduction; -, reduction; (-), weak reduction; =, almost no change; (+), weak increase; +, increase; ++, large increase. Numbers in parentheses refer to the positions concerned, and the molecules are classified according to increasing k' values. DIW, dichloromethane-isopropanol-water; CIW, cyclohexane-isopropanol-water; MW, methanol-water; AW, acetonitrile-water.

usually remains the same. Aminopropyl (APS) columns may interact specifically with 3-oxoecdysteroids and therefore introduce a different selectivity. C_2 -bonded phases behave like weakly active silicas and give very symmetrical peaks; they may be of interest for very polar non-ionic ecdysteroids.

The retention times obtained with silica columns may decrease upon prolonged use, because water-containing solvents slowly deactivate the column. A reactivation cycle with anhydrous solvents: alcohol, dichloromethane, hexane, dichloromethane (50–100 mL each) allows an almost complete recovery of initial retention times.

Solvents UV monitoring of the HPLC effluent precludes the use of solvents such as ethyl acetate, benzene or acetone (such limitations were not encountered with TLC). The solvent is usually based on a chlorinated hydrocarbon (dichloro(m)ethane, chloroform) modified with an alcohol (methanol, ethanol or isopropanol). Water added just below saturation reduces peak tailing.

Dichloromethane- and cyclohexane-based mixtures display a different selectivity, as shown in **Figure 8**. Selectivity changes are particularly impressive when considering the pair $5\alpha/5\beta$, or compounds bearing a lactone ring on the side-chain. As cyclohexane-based mixtures are highly viscous, the working pressures may exceed 100 bar with analytical columns run at a flow-rate of 1 mL min^{-1} . Increasing temperatures to 50°C overcomes this drawback and results in about a 40% decrease of working pressure without affecting the separation.

NP-HPLC is rather inefficient for the separation of compounds with or without extra double bonds, whereas RP-HPLC allows their easy resolution.

Selectivity in RP-HPLC

Columns Many different types of column are available, which differ by the type (C_6 , C_8 , C_{18} , C_{22} , phenyl, CN, etc.) and extent (percentage of the carbon load) of bonding, and also by the porosity (6–30 nm) of the silica used. All these parameters influence the selectivity of the column, thus, ensuring reproduction of a separation described in the literature requires the same type of column. C_{18} (or ODS) bonded silicas are the most widely used column packings.

Solvents The most common RP-HPLC solvents contain water and either methanol or acetonitrile, although other organic modifiers (ethanol, isopropanol, butanol, etc.) can be used. Using a buffer instead of water, or adding 0.1% (v/v) trifluoroacetic acid often results in much improved separations, especially when ionizable ecdysteroids are present.

The relative retention of ecdysteroids differing by a single -OH group varies with the organic solvent of the mobile phase. Extra -OH groups generally increase the polarity; their effect depends both on their position in the molecule (**Figure 9**) and on the solvent system used.

Isopropanol–water mixtures provide the best separations for $5\alpha/5\beta$ pairs. Methanol is particularly efficient towards extra double bonds and gives a base-

line separation of 24,25-ene and 25,26-ene pairs. Higher temperatures increase efficiency, decrease pressure and result in a reduction of k with only limited effects on selectivity.

Supercritical Fluid Chromatography (SFC)

Supercritical carbon dioxide is a non-polar fluid and therefore SFC is more or less equivalent to normal-phase HPLC. The eluting power is increased by adding methanol to the fluid. Various types of packed columns can be used (Table 11), including silica or bonded silica; bonded silica is less retentive as is observed with NP-HPLC. Alternatively, fused silica capillary columns can be used.

A major advantage of SFC over HPLC is shorter retention times. The compounds elute as very sharp peaks and the sensitivity of detection is increased accordingly. A second advantage is the high transparency of carbon dioxide in the infrared (IR), which allows the use of FT-IR detectors. Furthermore, SFC is compatible with both flame ionization detec-

Figure 10 SFC of ecdysteroids on 5 μ m-cyanopropyl-bonded silica gel with carbon dioxide-methanol (9 : 1) as mobile phase at 3 mL min⁻¹, 60°C and 290 bar (sample from *Silene otites*). (Reproduced from Raynor MW, Kithinji JP, Bartle K *et al.* (1989) Packed column supercritical-fluid chromatography and linked supercritical-fluid chromatography-mass spectrometry for the analysis of phytoecdysteroids from *Silene nutans* and *Silene otites*. *Journal of Chromatography* 467: 292-298, with permission from Elsevier Science.)

tion (the universal detection used with GC) and mass spectrometry (interfacing causes far fewer problems than with HPLC). No derivatization is required, and this represents an important advantage over GC. SFC appears, therefore, to be an interesting compromise, but its use has been up to now limited to plant extracts containing particularly high concentrations of ecdysteroids. The easy removal of carbon dioxide after fraction collection represents an advantage for preparative uses. An example of the separation of ecdysteroids by SFC is given in Figure 10.

Table 11 Some SFC systems used for ecdysteroid analysis

Column	Solvent system
Normal phase (silica)	
Hypersil 5 μ m (10 cm \times 4.6 mm i.d.)	CO ₂ -MeOH (4 : 1) 300 bar, 80°C, 4 mL min ⁻¹
Bonded phases	
Spherisorb-CN 5 μ m	CO ₂ or CO ₂ -MeOH (9 : 1)
Spherisorb-ODS2 5 μ m	CO ₂ or CO ₂ -MeOH (9 : 1)

See Lafont *et al.* (1994b) for more details.

Gas Chromatography

Gas chromatography (GC) was first developed for ecdysteroids during the early 1970s. Despite the advantages of GC (especially in combination with the electron capture detector), concerning sensitivity and specificity compared with other techniques, its use for ecdysteroids has been limited. As a majority of bio-synthetic intermediates of the ecdysteroids are involatile, it is necessary to convert them into volatile trimethylsilyl ether derivatives. Derivatization is usually performed with either trimethylsilylimidazole (TMSI) or *N,O*-bis-trimethylsilyltrifluoroacetamide, although other more specialized derivatives have been used. Complete derivatization is not always obtained and a single ecdysteroid can give rise to several chromatographic peaks.

Not all ecdysteroids are suitable for GC even after silylation. Silylation of compounds such as cyasterone (which contains a lactone in the side-chain) can result in a variety of derivatives characterized either by long retention times or poor peak shapes. Some ecdysteroid conjugates such as coumarate esters, appear to break down to the free ecdysteroid during the silylation procedure.

Chromatographic Systems

Chromatography was first performed with packed columns (1–3 m long, 2 mm i.d.) containing non-polar stationary phases such as OV-1 and OV-101 coated on Gas Chrom Q and Gas Chrom P. Fused-silica columns (10–25 m long, 0.22 mm i.d.) now provide much better separations. A typical operation temperature for the columns is 280°C.

Flame ionization detectors (FID) allow detection limits in the nanogram range. Electron-capture detection (ECD) provides the best available sensitivity among chromatographic methods (5 pg), and GC coupled with MS gives structural information with as few as 0.1 ng of ecdysteroids (particularly important with animal extracts). However, the need for derivatization is such a drawback that this powerful method is seldom used for ecdysteroids nowadays.

Conclusion

HPLC is the most widely used method for the separation of ecdysteroids. At the present time, hyphenated techniques (HPLC-MS and HPLC-NMR) are developing and will provide particularly powerful tools for the analysis of ecdysteroid-rich (plant) samples in the future.

ECOLOGICALLY SAFE ION EXCHANGE TECHNOLOGIES

D. Muraviev, Autonomous University of Barcelona, Barcelona, Spain

Copyright © 2000 Academic Press

The industrial application of ion exchange (IE) is growing. In many instances IE can successfully replace existing large scale industrial processes which do not satisfy modern ecological standards. To be competitive, IE technology should be highly efficient and ecologically safe. The general scheme of standard IE processes comprises several auxiliary operations (besides IE treatment), listed in Table 1. Several approaches have been applied to eliminate some of these auxiliary operations and to improve the efficiency and ecological safety of the process through significant savings of chemicals and energy and reduction of waste.

One of these approaches is based on the application of dual-temperature IE processes which exploit the different affinities of the resin towards ions to be separated at different temperatures. The main advantage of dual-temperature IE comes from avoiding the use of auxiliary reagents which are conventionally required to displace (strip) the ions to be separated from the resin phase and to regenerate the ion exchanger. This last stage is known to be the main source of waste in IE technology (Table 1). In dual-temperature IE, both stages can be combined in one through the use of a thermo-stripping procedure. This allows the exclusion of auxiliary operations 4 and 5. Hence, essentially reagentless and wasteless separation processes can be designed.

Another route to avoid auxiliary operations (e.g. numbers 2 and 3; Table 1) is based on a combination of IE conversion and the product concentration processes into one stage. Frontal IE chromatography and reverse frontal separation can be applied for this purpose. In certain instances, both of these IE separation techniques allow the concentration of the target substance to a level exceeding its solubility at a given temperature. Moreover, this supersaturated solution (SS) remains stable for a long period, while after leaving the column it crystallizes spontaneously. This allows the design of a nearly ideal process where a crystalline product is obtained directly after the IE treatment. The tailored application of this phenomenon (discovered by Muraviev and known as ion

exchange isothermal supersaturation or IXISS) allows, in certain instances, for additional elimination of operations 4 and 5. Several examples of the tailored application of dual-temperature IE and IXISS effects to design ecologically safe IE technologies are given below.

IXISS-based IE Processes¹

The tailored application of IXISS to design highly efficient IE technologies is based on the use of the IXISS-active stripping agents, which must meet the following requirements:

1. The IXISS-active eluent must on the one hand bear the desired counterion to combine the desorption of the product with the regeneration of the ion exchanger. On the other hand, it must also contain an appropriate co-ion to provide the formation of a stable SS of a low solubility compound (the product) and to shift the IE equilibrium in the system to the desired direction. For example, the IE reaction of displacement of a divalent metal ion, M_1^{2+} (e.g. Mg^{2+} or Ca^{2+}), by a monovalent one, M_2^+ (e.g. Na^+), from a carboxylic cation exchanger can be written as follows:

The equilibrium in reaction 1 is characterized by the equilibrium coefficient, $K_{M_2}^{M_1}$:

$$K_{M_2}^{M_1} = \frac{Q_{M_2}(C_{M_1})^{1/2}}{(Q_{M_1})^{1/2}C_{M_2}} \quad [2]$$

where C and Q are the concentrations of ions in the solution and resin phases, respectively. For chloride media, $K_{M_2}^{M_1}$ is usually $\ll 1$. If reaction 1 proceeds in a carbonate medium, for example, when the resin in the M_1 form is treated with

Table 1 Basic auxiliary operations of standard ion exchange process

No.	Operation	Consumption of		Wastes (approx. % of total)
		Energy	Chemicals	
1	Preparation of stock solution	Low	Low	Up to 5
2	Concentration of solution after IE treatment (e.g. by evaporation)	High	Low	
3	Recovery of purified product (e.g. by crystallization)	Medium	Low	Up to 5
4	Regeneration of ion exchanger and auxiliary chemicals for reuse	Low/medium	High	Up to 80
5	Neutralization of waste before their disposal	Low	High/medium	Up to 10

M_2 carbonate solution (C_o , mol dm⁻³), it is coupled with the formation of M_1 carbonate, which can be described by the solubility product of M_1CO_3 ($L_{M_1CO_3}$), where:

$$L_{M_1CO_3} = C_{M_1^{2+}} C_{CO_3^{2-}} \quad [3]$$

If M_1CO_3 forms a stable SS, where it exists in an associated (molecular) form at a concentration C_M mol dm⁻³ exceeding γ times its solubility, C_s , at a given temperature, eqn [3] takes the following form:

$$L_{M_1CO_3} = C_{M_1^{2+}} (C_o - C_M) \quad [4]$$

By introducing $C_M = \gamma C_s$, and after substitution of $C_{M_1^{2+}}$ from [4] into [2], one obtains:

$$K_{M_2}^{M_1} = \frac{Q_{M_2}(L_{M_1CO_3})^{1/2}}{(Q_{M_1})^{1/2} C_o (C_o - \gamma C_s)} \quad [5]$$

As follows from eqn [5], at constant C_o , C_s and $L_{M_1CO_3}$, $K_{M_2}^{M_1}$ increases with γ and may reach sufficiently high value ($\gg 1$), as $\gamma \rightarrow C_o/C_s$. Equation [5] can be rewritten in a more general form for the displacement of the divalent metal ion from the resin with an IXISS-active stripping agent bearing a monovalent counterion as follows:

$$K_{Sss}^{Dis} = \frac{Q_{Dis} L_{Sss}^{1/2}}{(Q_{Sss})^{1/2} C_o (C_o - \gamma C_s)} \quad [6]$$

Here 'Dis' and 'Sss' superscript and subscript denote the displacer and the substance under supersaturation (the product), respectively; C_o is the concentration of the displacer solution, L is the solubility product of the target compound, C_s is the solubility of the product at a given temperature, and γ is the degree of supersaturation for the product solution. Relationship [6] is the fundamental equation describing the shift of IE equilibrium in IXISS systems of different types.

- The successful application of the IXISS effect requires, on the one hand, maximum stability of the

SS in the interstitial space of the column during the IE treatment cycle and, on the other hand, fast decomposition (crystallization) of this solution after its removal from the column. In the case of inorganic substances a unified interpretation of the IXISS phenomenon must be based on general principles of the aggregative stability of dispersion systems, adapted to the particular IE system.

- The following main factors may influence the stability of dispersions of precrystalline molecular aggregates in the interstitial space of a column: firstly, an effective charge of the polymolecular aggregate (micelle), which is due to the sorption of either counter- or co-ions on the particle surface; and secondly, the ionic strength of the medium, which may strongly influence the coagulation (crystallization) conditions. If, for example, an excess of co-ions exists in the interstitial space, the charge of the micelles will be the same as that of the functional groups of the ion exchanger. In this case, the sorption of the micelles on the surface of the ion exchanger beads becomes impossible and a stabilizing action of the resin bed towards SS can be expected. In contrast, in the presence of an excess of counterions, the charge sign of the precrystalline aggregates will be opposite to that of the functional groups and fast decomposition of SS must be observed due to the sorption of micelles on the surface of the ion exchanger, followed by crystallization of the component under supersaturation.

Manufacture of Chlorine-free Potassium Fertilizers²

The production of chlorine-free potassium salts (with minimum Cl⁻ admixture) such as K₂SO₄, and others, is of particular interest since it deals with the problem

² Adapted with permission from Muraviev D, Khamizov R, Tikhonov N *et al.* (1998). Clean ion-exchange technologies. I. Synthesis of chlorine-free potassium fertilizers by an ion-exchange isothermal supersaturation technique. *Industrial Engineering and Chemistry Research* 37: 1950–1955.

of effectively cultivating some chlorophobic plants (e.g. citruses, vegetables and herbs) which are adversely affected by high Cl^- concentration. Potassium sulfate is produced in substantial quantities in Europe by the Mannheim process from K_2CO_3 and H_2SO_4 or by reaction of H_2SO_4 with KCl . Both versions of the Mannheim process are complicated by problems of utilizing gaseous wastes (CO_2 and HCl). In the USA and some other countries, K_2SO_4 is manufactured by exchange reactions between potassium, sodium and magnesium salts by their dissolution and fractional crystallization. This latter process requires utilization of large volumes of liquid waste. The IE synthesis of K_2SO_4 from KCl and $\text{Na}_2\text{SO}_4 \cdot 10\text{H}_2\text{O}$ is based either on cation or anion exchange reactions:

Cation exchange synthesis

Anion exchange synthesis

In the first process, a sulfonate cation exchanger is first converted from the Na^+ into the K^+ form with dilute KCl solution (0.1 mol dm^{-3}), followed by desorption (stripping) of the product (K_2SO_4) with concentrated Na_2SO_4 solution (2 mol dm^{-3}). The second process starts with the conversion of a strong base anion exchanger from the Cl^- into the SO_4^{2-} form with dilute Na_2SO_4 solution ($\sim 0.25 \text{ mol dm}^{-3}$). K_2SO_4 is then produced during the stripping of sulfate ions with concentrated KCl solution ($\sim 3\text{--}4 \text{ mol dm}^{-3}$). The stripping of K_2SO_4 from the resins in both cases leads to the formation of an SS of K_2SO_4 with a degree of supersaturation, γ , of approximately 2. Nevertheless, K_2SO_4 does not precipitate in the column and remains as a stable SS at least for a period of several hours. At the same time, this SS crystallizes spontaneously following its removal from the column. The maximum efficiency of the first process (see eqns [7] and [8]) is achieved when the stripping of the product is carried out at 308 K, followed by crystallization of K_2SO_4 at 293 K to provide the highest difference in sodium and potassium sulfate solubilities inside the column. The second process (see

eqns [9] and [10]) appears to be more efficient when carried out at 282 K to minimize the solubility of K_2SO_4 in the solution collected.

The IE equilibrium in both systems is shifted to the right when using dilute KCl and Na_2SO_4 solutions at the first stages of both processes. Application of IXISS effect in the flowsheets of both processes allows the product formation stage to be improved due to the shift of IE equilibrium in reactions 8 and 10 to the right. This clearly follows from eqn [5], which can be rewritten for, e.g. $\text{SO}_4^{2-}\text{--Cl}^-$ exchange (see reaction [9]), in terms of the equilibrium separation factor α (usually written using either equivalent or equivalent fraction concentration scales):

$$\alpha_{\text{SO}_4}^{\text{Cl}} = \frac{q_{\text{Cl}}}{q_{\text{SO}_4}} \frac{K_D \gamma C_S}{C_o(C_o - \gamma C_S)} \quad [11]$$

Here K_D is the dissociation constant of K_2SO_4 . The same reasoning is applicable to interpret the selectivity reversal in the cation exchange system.

Another advantage of the IXISS-based synthesis of K_2SO_4 deals with the possibility of reusing the supernatants obtained after crystallization of K_2SO_4 as a displacer in the subsequent stripping cycles. For example, after separation of K_2SO_4 crystals, the supernatant obtained in the first process is fortified with Na_2SO_4 up to the desired concentration of sulfate ions (2 mol dm^{-3}) and is then directed to the next stripping cycle. A diagram of the cation exchange version of the process for the synthesis of chlorine-free potassium sulfate is given in **Figure 1**. The unit comprises two ion exchange columns operating intermittently in a loading (see eqn [7]) or displacement (see eqn [8]) mode of operation. The second stage (displacement) is carried out using an Na_2SO_4 (or a $\text{Na}_2\text{SO}_4\text{--K}_2\text{SO}_4$ mixture) solution at 308 K. The rinsing water produced after each stage is returned to the process and is used to dissolve either KCl (rinsing after loading) or Na_2SO_4 (rinsing after displacement). The NaCl effluent obtained after the loading stage is directed into the reverse osmosis unit, which produces desalinated water and NaCl concentrate, used to manufacture crystalline NaCl . The desalinated water obtained is returned to the process. Hence, the process is essentially wasteless and ecologically clean.

Decalcination of Mineralized Waters

A number of modern technologies include water treatment processes, which in many instances involve a calcium removal stage. IE methods are widely applied to solve this problem for low mineralized surface waters. The problem of processing highly

Figure 1 Flowsheet of process for cation exchange synthesis of chlorine-free potassium sulfate. (Reproduced from Muraviev D, Khamizov R, Tikhonov N *et al.* (1998). Clean ion-exchange technologies. I. Synthesis of chlorine-free potassium fertilizers by an ion-exchange isothermal supersaturation technique. *Ind. Eng. Chem. Res.* 37: 1950–1955, with permission from the American Chemical Society.

mineralized waters is far more complicated. For example, preliminary treatment of seawater prior to its further desalination requires extensive decalcination to solve the problem of gypsum formation on heater surfaces of distillers and clogging of membranes in reverse osmosis or electrodialysis units. Modern seawater-processing technologies, such as IE recovery of magnesium, also require preliminary removal of calcium.

The problem of calcium removal from seawater (and highly mineralized waters and brines) can be successfully solved by using an IXISS-based process on specially modified conventional (low cost) sorbents with enhanced selectivity for Ca^{2+} . The first requirement is dictated by the necessity for the efficient use of the sorbent capacity towards Ca^{2+} at \sim five-fold magnesium over calcium excess in the seawater under treatment. The second arises from the need to process 1000 m^3 of seawater to produce 1 ton of magnesium. For example, several successive treatments of zeolites (e.g. of A type) with seawater and a concentrated NaCl solution result in their stable modification due to irreversible sorption of Mg^{2+} . An average $\alpha_{\text{Mg}}^{\text{Ca}}$ value for the modified zeolite (from seawater) rises to ~ 27 in comparison with 4.5 for the unmodified sorbent. The sorbent removes virtually no Mg^{2+} from seawater, whereas Ca^{2+} uptake appears to be nearly equal to its capacity ($\sim 4 \text{ mmol kg}^{-1}$). At the same time, $\alpha_{\text{Na}}^{\text{Ca}}$ for the modified zeolite remains at a sufficiently low level (~ 3.6) to simplify its regeneration with sodium salt solutions

after the loading with Ca^{2+} . The most efficient desorption of Ca^{2+} from zeolite is achieved by using an NaCl– Na_2SO_4 mixture. The reaction of Ca^{2+} – Na^+ exchange is coupled in this case with the reaction of CaSO_4 formation and, as a result, the equilibrium in the system is shifted to the right. The overall desorption process is described by the following equation:

The optimal molar ratio of Na_2SO_4 to NaCl (x/y in eqn [12]) in the regenerating solution is 0.2. In this case the regeneration of zeolite requires a close to stoichiometric amount of the regenerating agent. The eluate obtained during the stripping stage (Figure 2) is supersaturated ($\gamma \approx 5$). Nevertheless, it coexists with the granulated sorbent phase for a long period ($\sim 24 \text{ h}$ at 293 K) as a stable SS. This solution spontaneously crystallizes following removal from the column with the formation of gypsum, which is the only waste product in the process. After removal of the CaSO_4 precipitate by filtration, the supernatant can be fortified with the desired amount of NaCl– Na_2SO_4 mixture and returned to the process for reuse. The process is carried out in a two-fixed bed column set-up. The columns operate intermittently in a calcium removal and regeneration mode.

Figure 2 Desorption of Ca^{2+} from modified zeolite A with $1.25 \text{ mol L}^{-1} \text{ NaCl} + 0.25 \text{ mol L}^{-1} \text{ Na}_2\text{SO}_4$ mixture (circles). Triangles, calcium concentration in supernatant after crystallization of supersaturated solution samples. (Modified with permission from Muraviev *et al.*, 1998).

Recovery of High Purity Magnesium Compounds from Seawater³

The traditional magnesium-from-seawater technology includes mixing the raw seawater with 'milk of lime' filtration of $\text{Mg}(\text{OH})_2$ slurry, followed by its treatment with HCl , evaporation, drying and electrolysis. The process does not allow for producing sufficiently pure Mg . The possibility of designing an alternative IXISS-based process for recovery of high purity Mg compounds from seawater has appeared from the discovery of IXISS of MgCO_3 in the resin bed. The IXISS effect is observed during elution of Mg^{2+} from carboxylic resin pre-loaded with decalcinated seawater with a solution of Na_2CO_3 – NaHCO_3 mixture. Magnesium carbonate does not precipitate in the column and remains as a stable SS (with $\gamma \approx 5$) at least over a period of 72 h. After removal of this solution from the column (Figure 3), the desorbed magnesium spontaneously crystallizes in the form of well-shaped nesquegonite ($\text{MgCO}_3 \cdot 3\text{H}_2\text{O}$) crystals. The purity of magnesium compound obtained appears to be $> 99.9\%$ since, unlike magnesite

Figure 3 Concentration-time history of desorption of Mg^{2+} with $1.5 \text{ mol L}^{-1} \text{ Na}_2\text{CO}_3 + 0.60 \text{ mol L}^{-1} \text{ NaHCO}_3$ (circles) from carboxylic resin pre-loaded with decalcinated natural seawater at 293 K. Triangles, Mg^{2+} concentration in supernatant after short-term heating (during 10 min from 290 to 310 K) followed by crystallization of supersaturated solution samples. (Reproduced from Khamizov R, Muraviev D, Tikhonov N *et al.* (1998). Clean ion-exchange technologies. II. Recovery of high-purity magnesium compounds from seawater by an ion-exchange, isothermal supersaturation technique. *Ind. Eng. Chem. Res.* 37: 2496–2501, with permission from the American Chemical Society.

(MgCO_3), nesquegonite crystals are calcium-free. The yield of $\text{MgCO}_3 \cdot 3\text{H}_2\text{O}$ depends on the conditions of crystallization of the SS collected. Thus, crystallization at ambient temperature over several hours gives $\sim 70\%$ yield of the product in one desorption cycle. A rapid increase of temperature in the crystallizer from $\sim 290 \text{ K}$ to $\sim 310 \text{ K}$ over 10 min) allows for a substantial increase in the rate of crystallization, which results in the rise of the product yield to $> 90\%$.

The block scheme of the pilot unit for recovery of high purity MgCO_3 from seawater is shown in Figure 4. Ca-free seawater (see previous section) passes from the top to the bottom through two of the three columns C_1 – C_3 , loaded with carboxylic resin in the Na form. At the same time the third column is working in the regeneration (magnesium-stripping) mode of operation. After conversion of resin in the Mg form the columns are treated from the bottom to the top with a stripping solution of $1.5 \text{ mol L}^{-1} \text{ Na}_2\text{CO}_3 + 0.6 \text{ mol L}^{-1} \text{ NaHCO}_3$ mixture (also containing a residual MgCO_3 from the recycled stripping solution). Ca-free seawater, displaced from the columns, is directed to tank T_1 until the appearance of supersaturated eluate which, in turn, is directed to tanks T_2 and T_3 (crystallizers supplied with heating and filtration facilities to collect the crystalline product) by reswitching the automatic valve V_1 . After crystallization and removal of magnesium carbonate,

the stripping solution is returned to tanks T_4 and T_5 for fortification with the desired amount of the Na_2CO_3 – NaHCO_3 mixture from T_6 and reuse. Then the sorption cycle is repeated. The stripping solution displaced from the columns is also returned to T_4 and T_5 until the appearance of treated seawater in the line that is controlled by the automatic valve V_2 . Hence, the process shown in Figure 4 is totally free of waste.

Dual-temperature IE Processes

The efficiency of the dual-temperature IE process is primarily determined by the temperature sensitivity of the IE system which, in turn, depends on the value of the heat effect of a given IE reaction. The thermodynamics of a reversible IE reaction in the system including, for example, counterions A^{z_A+} and B^{z_B+} , a co-ion X^{z_X-} and a cation exchanger R bearing univalent functional groups can be described by the

Gibbs–Helmholtz equation:

$$\Delta G = \Delta H + T \left(\frac{\partial \Delta G}{\partial T} \right)_P \quad [13]$$

and the isotherm of an IE reaction by:

$$\Delta G_{P,T} = \Delta G_T^\circ + RT \ln \left(\frac{a_{AR}^{-1/z_A} a_{BX}^{1/z_B z_X}}{a_{BR}^{-1/z_B} a_{AX}^{1/z_A z_X}} \right) \quad [14]$$

where $\Delta G^\circ = -RT \ln K$, and K is the thermodynamic equilibrium constant of the IE reaction corresponding to the condition $\Delta G_{P,T} = 0$.

Eqns [13] and [14] lead to the van't Hoff equation:

$$\left(\frac{\partial \ln K}{\partial T} \right)_P = \frac{\Delta H}{RT^2} \quad [15]$$

Under standard conditions (when K depends only on temperature), eqn [15] can be rewritten in conventional derivatives and then integrated from T_1 to T_2 .

In the simplest case, when ΔH is independent of temperature, one obtains:

$$\ln \frac{K_{T_2}}{K_{T_1}} = -\frac{\Delta H}{R} \left(\frac{1}{T_1} - \frac{1}{T_2} \right) \quad [16]$$

The resulting relationship [16] is widely used to describe dual-temperature IE processes.

Concentration of Magnesium and Bromine from Seawater

At present, around 25% of overall world production of magnesium and 70% of that of bromine is provided from the sea and other hydromineral resources. Traditional methods for producing Mg (see previous section) and Br (air-stripping technique) by processing seawater, despite their profitability, do not satisfy increasingly stringent ecological standards. Consequently, new alternative ecologically clean technologies, based on IE separation methods, have to be developed. The dual-temperature IE concentration of Mg and Br from seawater is based on the strong temperature dependence of the separation coefficients α_{Na}^{Mg} and α_{Cl}^{Br} of weak acid (for Mg) and strong base (for Br) IE resins, respectively. For example, the α_{Cl}^{Br} value decreases by a factor of ~ 2 , while α_{Na}^{Mg} value increases by a factor of ~ 1.2 when the temperature of seawater rises from 283 to 363 K. The principle of the dual-temperature concentration of Mg and Br by using a cascade of fixed-bed columns is shown in Figure 5. The first column is intermittently treated with hot and cold seawater depending on the mode of

operation, e.g. thermosorption or thermostripping. Respective concentration–volume histories are shown in Figure 6 for the Mg concentration process. The resulting eluate is either collected in tank Conc. 1 (Mg or Br concentrate after thermostripping) or returned to the sea (after thermosorption). The concentrate obtained after the first column is subjected to the same sequence of operations on the second column to produce the second concentrate, and so forth.

In a subsequent treatment of cold and hot seawater in a fixed-bed IE column, the concentration of Br^- in the hot stripping solution increases by a factor of 2, while the concentration of Cl^- and SO_4^{2-} decreases. The multistage process (using AV-17 anion exchange resin, Reakhim, Moscow, Russia, Russian analogue of strong base anion exchangers such as, e.g. Dowex-1, Amberlite IRA 400, Purolite A 400 and Lewatit M 500) enriches Br^- concentration in the final concentrate up to an acceptable level for further processing ($> 5 \text{ g L}^{-1}$). Four dual-temperature sorption-stripping cycles (using Lewatit R 250 K resin, Bayer, Germany) allow for concentrating Mg up to $\sim 0.4 \text{ mol dm}^{-3}$ (versus 0.11 mol dm^{-3} in the initial seawater), as shown in Figure 7. The final concentrate can be decalcinated and used for producing high purity magnesium (see above). The resins used in both processes do not require any regeneration. Hence, the processes are completely free of waste products.

Reduction in energy expenditure for heating the seawater can be successfully solved by using conventional, or concentrated, sunlight (in areas with a high level of solar radiation) as the principle and

ecologically clean energy source (sun-boiler systems). An alternative solution can be the use of seawater in the cooling cycles of steam power stations. The amount of seawater pumped through the cooling cycles of these stations is approximately $20\,000\text{--}30\,000\text{ m}^3\text{ h}^{-1}$. This hot seawater is currently pumped back into the sea, which means that billions of joules of heat are wasted. This seawater could be used

Figure 7 Concentration of Ca^{2+} (circles), Mg^{2+} (squares) and Na^+ (triangles) obtained in consecutive thermostripping-sorption cycles vs number of cycles. for recovering minerals (e.g. Mg and Br). In this way, the power costs in heating seawater and moving it through the mineral recovery process (which substantially exceeds 50% of the overall expenditures for electricity) could be written off.

Concentration of Copper from Acidic Mine Waters⁴

The treatment of acidic mine waters (AMW), representing natural effluents from pyritic ore deposits, is of great economic and ecological importance. The AMW are characterized by low pH (~ 2) and relatively high concentrations of metal ions such as Fe^{3+} , Zn^{2+} and Cu^{2+} (Table 2). The initial AMW requires pre-conditioning by selective removal of iron prior to IE treatment. This conditioning is carried out by adjusting the pH to 3.4–3.5 with alkali followed by either conventional or biooxidation of Fe(II) to Fe(III). The final removal of the $\text{Fe}(\text{OH})_3$ precipitate is carried out by filtration.

Two commercial IE resins, namely a polyacrylic (e.g. Lewatit R 250-K) and an iminodiacetic (e.g.

Lewatit TP-207) can be used for the dual-temperature IE concentration of copper from AMW. Acrylic resin is selective for Al³⁺ (over other AMW metal ions) and iminodiacetic resin manifests high selectivity towards Cu²⁺. The uptake of Al³⁺ increases remarkably while that of Cu²⁺ decreases with temperature for both resins and that for the rest of the metals depends weakly on temperature. This effect gives the possibility for the dual-temperature IE concentration of copper from AMW by using the same set-up and the mode of operation as shown in Figure 5. The resins are first equilibrated with cold AMW (at 293 K). Then a selective thermostripping of Cu²⁺ is carried out using hot AMW (at 353 K), leading to an increase in Cu²⁺ concentration in the eluate by a factor of 1.3 (for acrylic resin) or 1.2 (for iminodiacetic resin). The concentration of Al³⁺ in the same eluate drops to 50% in the first case and to 70% in the second. The efficiency of both thermosorption and thermostripping processes (at constant solution flow rates and resin bed heights) depends on the interval of working temperatures (see eqn [11] and is higher the greater this interval (Figure 8).

The concentration of Cu²⁺ achieved after the fourth thermosorption–thermostripping cycle increases (in comparison with the initial AMW) by a factor of ~3, while that of Al³⁺ decreases by one order of magnitude (Figure 9). The substantial increase in the efficiency of the process (higher degree of concentration) can be achieved using either higher fixed resin bed columns (see Figure 5) or a cascade of countercurrent columns, as shown in Figure 10. The unit comprises several two-section countercurrent columns which are operated at different temperatures to provide thermosorption/ thermostripping conditions in the sections. The first column is fed by the native AMW and produces the first concentrate, which is collected from the boundary between sections and then directed to the bottom section of the second column and so on. The resin in all columns circulates in a closed cycle and does not require regeneration. The unit shown in Figure 10 can also be used for the dual-temperature IE processing of seawater to

produce magnesium or bromine concentrates in a continuous mode of operation.

Concluding Remarks

The number of large scale industrial applications of both dual-temperature IE and IXISS-based IE processes is still very limited. For example, the dual-temperature partial demineralization of surface waters using specially synthesized polyampholyte resins (so-called Sirotherm process) so far remains the only industrial application of dual-temperature IE. At present, a large scale pilot plant using the counter-current version of an IXISS-based process for the recovery of more than 300 tons of high purity magnesium carbonate from seawater per year has started operation in the Vladivostok region of Russia. The unit shown in Figure 4 adequately imitates the basic flowsheet of Vladivostok plant in the fixed-bed mode of operation.

The prospects for wider implementations of ecologically clean IE processes in different fields of industry are primarily determined by their obvious advantages and relative simplicity. For example, the use of IXISS effect in the design of highly efficient and ecologically safe IE technology does not require any specific IE equipment and can be easily realized using standard IE columns. At the same time, a deeper insight into the IXISS phenomenon can substantially widen the area of practical application of this effect. In this regard, the solution of the following problems seems to be of particular importance:

1. Identification of chemical compounds (both organic and inorganic) exhibiting IXISS effect (IXISS-active compounds)
2. Evaluation of stabilizing efficiency of commercially available IE materials towards SS of IXISS-active compounds of different types (electrolytes, nonelectrolytes, polyampholytes and zwitterlytes)
3. Development of theoretical fundamentals of IXISS effect and some others

Figure 8 (A) Thermostripping and (B) thermosorption break-through curves for Cu^{2+} and Al^{3+} obtained from native AMW (see Table 2) on iminodiacetic Lewatit TP-207 resin at various thermostripping temperatures: 313 K (circles); 333 K (squares); 353 K (triangles). Thermostripping is carried out at indicated temperature after loading of resin at 293 K. Thermosorption is carried out at 293 K after finishing the thermostripping cycle at the indicated temperature. (Reproduced from Muraviev D, Noguerol J and Valiente M (1997) Application of the reagentless dual-temperature ion-exchange technique to a selective separation and concentration of copper versus aluminium from acidic mine waters. *Hydrometallurgy* 44: 331–346, with permission from Elsevier Science.

Several recent publications and reviews by the author are recommended to those interested in this subject.

Unlike IXISS-based IE processes, large scale industrial applications of dual-temperature IE requires in

certain instances the design of special IE equipment such as, for example, two-sectional jacketed IE columns providing the dual-temperature mode of operation. At the same time, it seems useful to emphasize that the shift of chemical equilibrium to the desired direction due to the modulation of temperature in the system represents one of the basic physicochemical concepts which are widely used in different fields of chemical technology. From this viewpoint the dual-temperature IE cannot be considered as a somewhat exotic separation method as in many instances the experience (both theoretical and experimental) accumulated in other areas of chemical science and engineering can be successfully applied for the further development of this fractionation technique. On the other hand, it seems useful to distinguish the following problems, the solution of which can help to widen the application of dual-temperature IE in industry:

1. the evaluation of temperature sensitivity of commercially available ion exchangers towards different ionic systems of practical interest to estimate their potential use in dual-temperature IE processes
2. the tailored design and synthesis of temperature-responsive IE resins tuned for the dual-temperature IE fractionation of certain ion mixtures. Ion exchangers of this type are not so far commercially

Introduction

Electrochemical ion exchange (EIX) is a process where electrochemistry and ion exchange (IX) are combined to effect the separation of ions more efficiently than the use of either technique alone, especially in minimizing secondary waste generation. The varieties of EIX, beginning with those using electrochemically inactive IX materials and proceeding to those using electrochemically active ion exchange (EaIX) materials, are discussed here.

EIX Processes Using Electrochemically Inactive Ion Exchange Materials

Some materials used in the EIX process are not active electrochemically, that is, they do not contain functional groups that can be reduced or oxidized. Examples of commonly used separation techniques of this type include *electrodialysis* and *electrophoresis/electrochromatography*. In electrodialysis, the permselectivity of IX membranes is used in combination with an electric field to separate anions and cations. In a variation of conventional electrodialysis called *electrodialysis polishing*, IX materials are packed between the IX membranes; the IX material serves as an immobile electrolyte. The schematic of the process shown in **Figure 1** shows that the water is processed through the IX materials. Due to the high concentration of ionic sites in the IX material, fairly resistive (up to 15 MΩ) water can be produced at the outlet. In electrophoresis/electrochromatography where IX packing materials are used, IX interactions between the analyte and the column material enhance the separation capability over that available if differences in electrophoretic mobilities alone were used.

Another process in this category, a process termed *EIX* by the original researchers (Allen *et al.*), uses an assembly consisting of an electrochemically inactive IX material attached to an electrode as the separation agent. This approach, for the separation of cations, is shown in **Figure 2**. (It should be noted that the term

'EIX' is used more broadly here to denote a set of separation techniques that use electrochemistry and IX, not just the process shown in **Figure 2**.) Here, a cathodic potential is applied to the electrode material assembly for the uptake of cations. The applied potential serves to generate an electric field that increases the transport rate of cations toward the electrode material assembly and to electrolyse water to produce hydroxyl ions that activate the IX material. To elute the sorbed cations, an anodic potential is applied to the electrode/cationic ion exchange material assembly. This results in the local

Figure 1 Cationic and anionic IX resins are depicted as hatched and open areas, respectively. Only cations are mobile in the cationic IX material, and only anions are mobile in the anionic IX material. Cations in the feed water are expelled from the water while flowing through the cationic IX material. Similarly, anions are expelled from the feed water while flowing through the anionic IX material.

Figure 2 Cation uptake (top) and elution (bottom) at the EIX electrodes. Water reduction leads to production of hydroxyl ions resulting in the de-protonation of sites in the cationic IX resin. In turn, the IX resin will uptake cations to maintain electroneutrality. The electric field, E , present during the water-reduction process, serves to enhance cation transport to/within the cationic IX resin. The reverse reactions occur during cation elution.

production of hydrogen ions from the splitting of water, which in turn displaces the sorbed cations as in conventional IX processes. In addition, an electric field is generated which accelerates the transport rate

of cations. For anions, anionic IX materials are used; an anodic potential is applied to the assembly during uptake and a cathodic potential is applied during elution. The advantages of this approach over conventional IX processes are increased uptake rate due to the applied electric field and more efficient use of hydrogen or hydroxyl ions for both uptake and elution. Although the thermodynamics of the elution process have not changed as compared to conventional IX, the close proximity of the generated hydrogen or hydroxyl ions to the exchange sites increases the overall process rate by reducing the time required for uptake and elution. In addition, fewer excess hydrogen or hydroxyl ions are required.

EIX Processes Using Electroactive Ion Exchange Materials

Figures 3(A) to (D) show conceptually the electroactive ion exchange (EaIX) approach, a subset of EIX techniques. Here, EIX processes, where EaIX materials are used, will be denoted as EIX/EaIX. Figure 3(A) and (B) illustrate cation separation. The reduction of a generic EaIX material, X , results in a net negative charge that has to be compensated by a cation (see Figure 3A). Provided that X is selective

Figure 3 (A) Cation intercalation/uptake during film reduction. (B) Cation de-intercalation/elution during film oxidation. (C) Anion intercalation/uptake during film oxidation. (D) Anion de-intercalation/elution during film reduction.

for a specific cation, then the cation uptake shown in **Figure 3(A)** results in the selective separation of a cation, M_1^+ , from, say M_2^+ . Elution of M_1^+ is simply achieved by oxidizing X^- back to X , which is necessarily accompanied by the expulsion of M_1^+ (see **Figure 3B**). The analogous uptake and elution of anions are shown in **Figure 3(C)** and **(D)**, respectively. For anions, uptake occurs during oxidation, and elution accompanies reduction. It should be noted that the same sequence of oxidation and reduction is used for the EIX/EaIX approach and the process shown in **Figure 2**. More importantly, however, the two approaches are very different with respect to the specific electrochemical reactions that take place during oxidation and reduction. In the process shown in **Figure 2**, both oxidation and reduction reactions are water-splitting. The reductive water-splitting results in hydrogen gas and hydroxyl ion production, whereas the oxidative water-splitting results in oxygen gas and hydrogen ion production. While this approach results in relatively efficient use of the protons and hydroxyls, the exchange ratio is not one to one. That is, more than one equivalent of protons is required to displace one equivalent of cations (or uptake one equivalent of anions). In addition, in the processing of radioactive materials, hydrogen gas generation is undesirable because of safety issues. On the other hand, with the use of EaIX materials (as shown in **Figure 3A** to **D**), only one equivalent of electrons is needed to elute one equivalent of ions. Therefore, using EaIX materials further reduces the amount of secondary waste generated. The electric field generated within EaIX materials has two functions: firstly to increase the transport rate of ions through the EaIX material and secondly to attract (or expel) the ions to the binding sites since the electric field is strongest near an oxidized or reduced site. The last point is particularly noteworthy since it implies that highly selective materials can be used. Although the requirements of high selectivity and ease of elution are typically in conflict, the two requirements are not mutually exclusive if the elution is purely electrostatic in nature.

EaIX materials have been applied for analytical-scale separation in a process called *electrochemical chromatography*. This process is very similar to conventional liquid chromatography except that the stationary phase is electroactive. As in conventional chromatographic processes, the retention times for different ions are largely controlled by interactions with the stationary phase. However, the redox state of the stationary phase allows additional control of the interactions between the analytes and the stationary phase. For example, anions can be easily separated from cations by applying a positive or anodic potential to the stationary phase. Separation of the different an-

ions, however, still relies on the specific interactions between the stationary phase and the ions.

EaIX materials may also be used for preparative-scale separations. Two modes of operation are possible: packed bed and membrane. The sequence of operational events in the packed bed mode in EIX/EaIX is a combination of the sequences used in electrochemical chromatography and conventional IX processes: firstly, analyte is sorbed into the EaIX material during the uptake cycle (with or without the application of a potential) and secondly the sorbed ions are eluted from the EaIX material by the application of a potential (see **Figure 4**). It should be noted that EaIX materials can be used as conventional IX materials during the sorption cycle; the distinguishing feature of the EaIX material is the ability to elute sorbed ions by simply applying the appropriate potential (**Figure 3B** and **D**). In the second mode of operation, the EaIX materials are made as membranes (see **Figure 5**). This mode of operation is superior to the packed-bed approach since solution switching is not required. This in turn implies that continuous operation is possible and that neither the process nor waste stream will be diluted, which necessarily occurs when solution switching takes place in the packed-bed mode. On the other hand, the packed-bed mode is more advantageous in treating very

Figure 4 EIX/EaIX columns consist of the EaIX electrodes and counterelectrodes. Connections to the elution solutions are closed during sorption of target ions from the process waste stream. Sorption can be with or without an applied potential (see eqns [2] and [3] in the text). Elution is achieved by applying a potential (see **Figure 3B** and **D**) and flowing the elution solution.

Figure 5 The EalX membrane is always an electrode when used in the membrane mode. (A) Reduction of EalX membrane (negative electrode) results in uptake of cations from the treated stream. (B) Oxidation of EalX membrane (positive electrode) results in elution of cations to the waste stream. The treated and waste streams never come in contact.

dilute streams since more intimate contact between the process stream and the EalX materials is possible. In addition, there are possibly more difficulties associated with preparing EalX materials as membranes than as packed-bed materials.

Characterization of EalX Materials

In the development and testing of an EIX/EalX process, the ion-loading capacity and specific ion selectivity of the EalX materials are of particular interest. Selectivity is defined in terms of a separation factor α_1^2 , which describes the selectivity for species '2' over species '1':

$$\alpha_1^2 = \frac{x_2'/x_1'}{x_2/x_1} \quad [1]$$

The numerator is the ratio of ion mole fractions within the EalX material, and the denominator is the mole fraction (or concentration) ratio in the bulk binary solution contacting the EalX material. The separation factor is especially useful for estimating process performance. For example, Figure 6 shows the fraction of Na^+ recovered as a function of K^+ removed for various values of α_{Na}^K . The plots show that if a minimum of 90% Na^+ recovery is required while expelling $>70\%$ of the K^+ , then an α_{Na}^K of approximately 30 is needed.

Electrochemical Methods

In addition to standard bulk contact methods typically used to characterize IX materials, electrochemical methods are well suited for evaluating EalX materials, especially for evaluating their expected performance when an applied potential is used in the uptake cycle. Two conventional electrochemical methods – *cyclic voltammetry* and *chronoamperometry* – are particularly useful in evaluating the ion-loading capacity of EalX materials. Cyclic voltammetry is best suited for a planar geometry since

Figure 6 Fraction of Na^+ recovered as a function of K^+ removed for various separation factor, α_K^{Na} .

the slowly ramped applied potential is less intrusive on the samples. Chronoamperometry, on the other hand, is more suitable for determining the capacity of EaIX materials deposited on a high-surface area electrode because mass transfer limitations affect measured cyclic voltammograms (CVs).

A CV is obtained by measuring the current passed at the electrode as the applied potential is swept linearly at a fixed scan rate between two potential limits. When a suitable potential window is selected, cations (anions) are loaded into the EaIX material during the cathodic (anodic) sweep and the ions are eluted during the reverse sweep. The total charge passes in a load or unload cycle, as determined by integrating the current over any linear sweep, is a direct measure of the ion-loading capacity when the charge transfer is only a result of a known electrochemical reaction (see eqn [2] below). In chronoamperometry, the potential is stepped from one potential limit to the other. The current is measured while the potential is held at a limit for a fixed period of time, and again, the integrated charge passed is a measure of the ions loaded into or eluted from an EaIX electrode assembly.

Electrochemical and Gravimetric Methods

The two electrochemical methods described above yield only the ion-loading capacity. In order to determine the separation factor, an additional independent measurement is required. This is accomplished by combining the electrochemical measurements with gravimetric measurements. A common term for this combined method is electrochemical quartz crystal microgravimetry (EQCM). As the name suggests, mass accumulation within the EaIX material is monitored in addition to the total charge passed. Typically, quartz crystals are coated with an electrode on which a layer of an EaIX material is deposited. The fundamental frequency of the crystal is very sensitive to the mass loaded in the EaIX material; monitoring this fundamental frequency, the mass loaded during uptake and elution can be determined. For a crystal oscillating at 5.9 MHz, a 1 Hz decrease in the frequency corresponds to a mass increase of $\sim 4.0 \times 10^{-9}$ g. In EQCM, the oscillation frequency is monitored at the same time that the potential is swept to obtain a CV. This combination of measurements gives simultaneous information on electrochemical (ion) capacity and mass changes during load and elution cycles. Since mass change differs according to the molecular weight of the ions transported in and out of the EaIX film, the selectivity of the EaIX material for an ion in a binary mixture of known composition can be determined using EQCM. The

analysis is complicated, but not prohibitively, by the simultaneous transport of solvent (e.g., hydration water) and other species with the ions of interest.

Flow Cell Methods

Flow cell methods for EIX/EaIX characterization differ from conventional IX methodologies only in the material preparation. To achieve high volumetric ion-loading capacity, EaIX materials are typically coated on high surface-area electrodes (e.g., porous metal foam or mesh). These EaIX electrodes can be used in any of the modes represented in eqns [2] and [3]. To create an EaIX bed, multiple porous electrodes are used in series (see Figure 7A and B). When used in the conventional mode in the uptake cycle, the process stream simply flows through the electrodes. The effluent solution composition is analysed and breakthrough curves are obtained.

Properties of EaIX Materials

Functional requirements of EaIX materials are electronic conductivity, ionic conductivity, selectivity for the ion of interest, and reasonable stability (physical and chemical). Of the numerous inorganic and organic materials that fulfil all or some of the listed requirements, discussions will be limited to nickel hexacyanoferrate (NiHCF) as an example of a cationic EaIX material and polyvinylferrocene (PVF) as an example for an anionic EaIX material.

Hexacyanoferrate materials (including NiHCF) are known to be selective for alkali metals and, in

Figure 7 (A) Single electrode with the associated spacers and gaskets. (B) Eight-stack cell used for flow-through studies.

Figure 7 Continued

particular, are extremely selective for cesium (Cs^+) over sodium (Na^+) and potassium (K^+). More recently, the preference of polyvinylferrocene for perchlorate (nonradioactive chemical analogue of pertechnetate) anions over nitrate anions has been demonstrated.

Nickel Hexacyanoferrate

Nickel hexacyanoferrate $[\text{Ni}^{\text{II}}\text{Fe}^{\text{II/III}}(\text{CN})_6]^{2-/-}$ (NiHCF), an electroactive material, is known to complex reversibly with the alkali metal cations such as Na^+ , K^+ , and Cs^+ . Upon reduction of the iron (Fe^{III})

centre in NiHCF, an alkali cation associates with the ferrocyanide moiety to maintain charge neutrality through the following reaction, where M^+ is an alkali metal cation:

The reverse reaction, upon oxidation of the Fe^{II} centre, results in the dissociation of a single alkali metal cation per molecule of hexacyanoferrate. Oxidation of NiHCF film deposited on a substrate electrode, therefore, leads to the expulsion or

deintercalation of alkali cations from the film into a contacting solution, while the reduction of deposited NiHCF film leads to the uptake or intercalation of alkali cations from solution into the film (see Figure 3B and A, respectively). The selectivity for alkali cations M^+ by NiHCF increases with molecular weights, $Cs^+ \gg K^+ > Na^+$. Therefore, K^+ or/and Na^+ is readily exchanged for Cs^+ ; for example:

Equation [3] shows that the EaIX material can be used in conventional IX. The Cs^+ is bound so strongly that elution is only possible through oxidation of the Fe centre from II to III. Chemical oxidation has been demonstrated with NiHCF as well as for the copper and zinc analogues. Approximately five column volumes of 8 mol L^{-1} nitric acid are required for effective elution of all the sorbed Cs^+ . The cost and hazard associated with this eluent are significant. Use of the EIX/EaIX approach, therefore, provides an attractive alternative since the oxidation can be done more efficiently via the electrochemical approach.

It is imperative for the EIX/EaIX process that there is intimate contact between the EaIX material and the electronically conducting substrate. NiHCF can be conveniently deposited onto a conducting substrate electrochemically. A nickel surface corroded in a solution containing hexacyanoferrate ions results in the precipitation/deposition of NiHCF on the surface. The electrochemical route is particularly advantageous over other methods (e.g., precipitation and sol-gel) since deposition within the pores of a porous electrode can be carried out readily.

Applications The selectivity of NiHCF for alkali cations with an affinity order $Cs^+ \gg K^+ > Na^+$ is attributed to the relative sizes of the ions, both hydrated and not, and the NiHCF cubic lattice structure that the ions must penetrate and then occupy. Because NiHCF is both electronically and ion conducting, is readily deposited as a film on conductive electrode substrates, and is alkali cation-specific, it is an ideal EaIX material for K^+ and Cs^+ separation applications.

Potassium separation The forest products industry requires selective removal of K^+ and recovery of Na^+ . As the plots in Figure 6 show, the separation factor is critical in determining the extent to which Na^+ can be recovered for a required removal of K^+ . Therefore, quantification of α_{Na}^K is essential for scale-up purposes and capital cost estimation. Because

equipment capital costs scale roughly with the electrode costs, it is necessary to minimize electrode area to make the EaIX process financially attractive. The larger the separation factor α_{Na}^K , the smaller the EaIX electrode area necessary to remove a given amount of K^+ . Electrode area is also reduced if the ion capacity of the EaIX material per unit electrode area is increased.

The selectivity of NiHCF for K^+ in preference to Na^+ was quantified by EQCM and by bulk-contact experiments. Separation factors α_{Na}^K ranged from about 5 using EQCM to a maximum of 24 in bulk-contact tests; these differences will be discussed further below. Figure 8(A) and (B) show the results of EQCM experiments for a NiHCF-coated quartz crystal in contact with potassium and sodium sulfate solutions and mixtures. The CVs in Figure 8(A) show

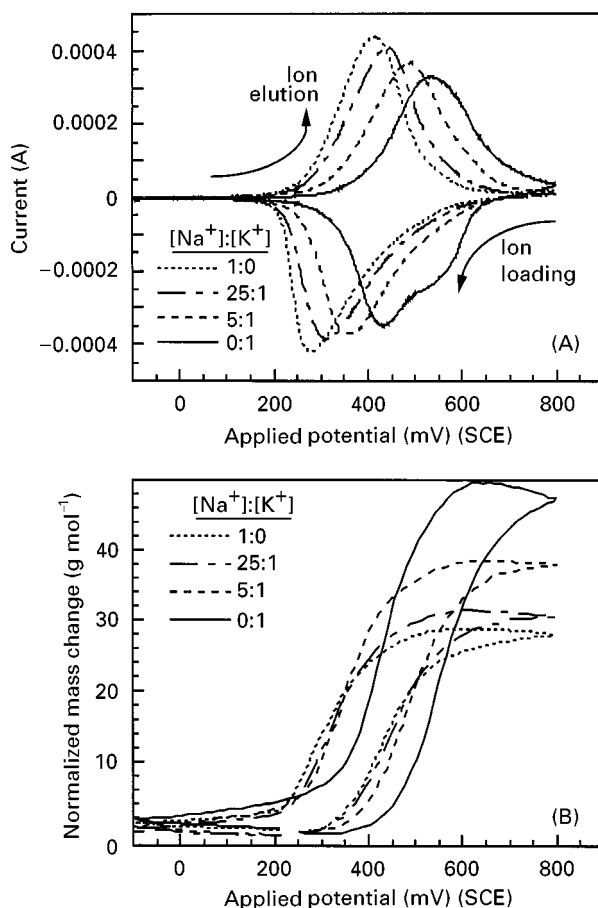

Figure 8 EQCM results for a series of $0.5 \text{ mol L}^{-1} \text{ Na}_2\text{SO}_4$ and $0.5 \text{ mol L}^{-1} \text{ K}_2\text{SO}_4$ solution mixtures demonstrating selectivity of a NiHCF film for K^+ over Na^+ : (A) Cyclic voltammograms indicate sensitivity to K^+ in solutions > 25 times more concentrated in Na^+ ; and (B) QCM mass data, normalized by the ion-loading capacity and converted to units of apparent molar weight, indicate greater mass changes as solutions become more concentrated in K^+ and relatively more K^+ is loaded into the film. the reversibility of the cation uptake (negative currents) and elution (positive currents). In addition, the area between the abscissa and either the negative or positive currents is proportional to the net ionic loading. Combined with the apparent molar weights shown in Figure 8(B), separation factors ranging from 3.8 to 5.9 were calculated (see Table 1). In addition to providing quantitative estimates of the separation factors, Figure 8(A) and (B) qualitatively show the preference of K⁺ over Na⁺. As the mixtures become more concentrated in K⁺, the peaks shift to higher potential, more in line with that of pure K₂SO₄ solution. Even in solutions five times more concentrated in Na⁺, the peaks shift substantially toward those for pure K₂SO₄ solution, indicating the relative selectivity of NiHCF for K⁺. The shift towards higher apparent molecular weights in the mixtures also indicates the preference for K⁺.

Bulk-contact tests of NiHCF, a more direct measure of selectivity, resulted in separation factors ranging from 14 to 24. Representative experimental details and results are shown in Table 2. In all the tests shown in Table 2, the Na⁺ : K⁺ molar concentration ratio was ~12, which is the approximate ratio of the ions in pulp mill application. The amount of K⁺ taken up by the NiHCF without any applied potential (IX mode, eqn [3]) was determined from the total solution volume and the difference in K⁺ concentration before and after contact. The sep-

aration factor, $\alpha_{\text{Na}}^{\text{K}}$, determined by this bulk-contact method, is very sensitive to the total capacity value. Since there are more uncertainties in determining the total capacity for the foam electrodes (in comparison to the small planar EQCM electrodes), the variability and uncertainty of bulk-contact separation factors obtained are greater. Despite the uncertainties associated with the total capacity, the batch-contact tests are in agreement with the EQCM results in that NiHCF materials are selective for K⁺ over Na⁺. The reason for the difference in the magnitude of the separation factors determined by the two techniques is presently unclear. Three possibilities are (1) differences in NiHCF film preparations resulting from differences in the electrode substrate on which they were deposited, (2) differences in solution ionic strengths (~1 mol L⁻¹ alkali for EQCM and < 0.1 mol L⁻¹ alkali for bulk contacting), and (3) the potential was applied to NiHCF in the EQCM experiments but not in the bulk-contact tests.

Cesium separation The radioactive isotope ¹³⁷Cs, a fission product of nuclear fuel processing and corrosion of fuel rods in commercial nuclear reactors, is a trace component of several process and waste streams in the nuclear industry. Because of the strong affinity of NiHCF for Cs⁺, separation of this ion by EIX/EaIX is ideal. Figure 9(A) and (B) show the EQCM results for dilute Cs⁺ in competition with excess Na⁺. The experiments are analogous to those described for K⁺ separation above, but the shifts toward pure Cs⁺ solutions observed in the mixtures are more pronounced.

Table 3 summarizes the apparent molar masses and separation factors $\alpha_{\text{Na}}^{\text{Cs}}$ for a series of Na⁺ : Cs⁺ mixtures. The separation factors range from 178 to 593, clearly demonstrating the enhanced selectivity of NiHCF for Cs⁺ relative to Na⁺ and K⁺ (compare to Table 1). Neglecting the results for the 81 Na⁺ : 1 Cs⁺ mixture, which had a higher estimated uncertainty, there appears to be a trend of increasing Cs⁺ selectivity with decreasing Cs⁺ concentration.

Table 2 NiHCF bulk-contact separation factors and experimental conditions. (NiHCF-coated circular disc electrodes ~5-cm diameter by ~0.6-cm thick, 80 pores inch⁻¹ porosity, and ~60 cm² cm⁻³ specific volume contacted with 18 mL of mixed ion solution)

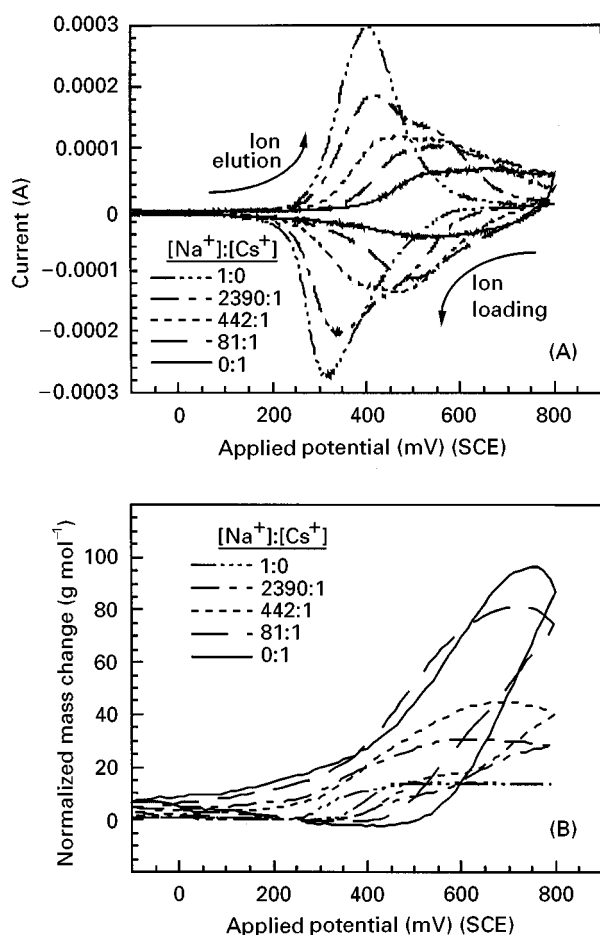

Figure 9 EQCM results for a series of 1.0 mol L⁻¹ NaNO₃ and 1.0 mol L⁻¹ CsNO₃ solution mixtures demonstrating selectivity of NiHCF film for Cs⁺ over Na⁺: (A) cyclic voltammograms indicate sensitivity to Cs⁺ in solutions ~2400 times more concentrated in Na⁺; and (B) QCM mass data, normalized by the ion-loading capacity and converted to units of apparent molar weight, indicate greater mass changes as solutions become more concentrated in Cs⁺ and relatively more Cs⁺ is loaded into the film. (Adapted, with permission from Rassat *et al.* (1999), Elsevier Science.)

In the limited range of K⁺ and Na⁺ mixtures tested, such a trend was not detected.

Flow-through EIX/EaIX experiments demonstrate the regenerability of the EaIX material without the use of highly oxidizing solutions. Breakthrough curves for a 0.2-ppm Cs⁺ feed stream are shown in Figure 10. Here, the EIX/EaIX system was operated in the conventional IX mode in the uptake cycle. The breakthrough curve for the first flow test shows that the breakthrough point (where the concentration of Cs⁺ in the effluent stream is one-half the feed concentration) occurs after ~110 bed volumes were passed in the first flow test. In subsequent flow tests, each following regeneration of the NiHCF electrodes, the breakthrough capacity was reduced to ~40 bed volumes and the breakthrough profiles were consistent.

Regeneration cycles were carried out by potential cycling in a solution of sodium nitrate. The reasons for the diminished breakthrough volume after the first cycle are presently unclear. It is speculated that this is a 'plugging' issue. One hypothesis is that because of the great affinity of NiHCF for Cs⁺ and strong binding in the cubic lattice, migration of Cs⁺ to all sites within the film is hindered, and therefore, some Cs⁺ are permanently bound in the NiHCF. The most noteworthy point is that regeneration of the EaIX material is reversible (starting with the second cycle) without the need for strong oxidiz-

Figure 10 Breakthrough curves for a feed stream of 0.2-ppm Cs in an EaIX bed consisting of eight NiHCF-coated porous nickel foam electrodes operated in IX mode. The electrodes were regenerated electrochemically in concentrated NaNO₃ solution between each test. Experimental conditions: 80 pores inch⁻¹ or ~60 cm² cm⁻³ nickel foam; CsNO₃ solution flowed at 24 mL min⁻¹; bed volume of ~39 mL; and maximum ion capacity ~2.0 C.

Figure 11 EQCM results for a series of 0.5 mol L⁻¹ NaNO₃ and 0.5 mol L⁻¹ NaReO₄ solution mixtures demonstrating selectivity of a PVF film for ReO₄⁻ over NO₃⁻: (A) cyclic voltammograms indicate sensitivity to ReO₄⁻ in solutions nine times more concentrated in NO₃⁻; and (B) QCM frequency shifts indicate greater mass changes as solutions become more concentrated in ReO₄⁻ and relatively more ReO₄⁻ is loaded into the film.

ing solutions (i.e., 8 mol L⁻¹ nitric acid used by previous researchers).

Polyvinylferrocene

Polyvinylferrocene $[-(\text{Fe}^{\text{II/III}}(\text{C}_5\text{H}_5)(\text{C}_5\text{H}_4\text{CH}_2\text{CH}_2)^{1+/0})-]$, or PVF, is a well-studied organometallic polymer. In contrast to NiHCF, oxidation of PVF to the 1+ state requires the uptake of anions to maintain electroneutrality (see Figure 3C), making PVF a suitable anionic EaIX material candidate. Recently, the preference of PVF for perrhenate (ReO₄⁻) over nitrate (NO₃⁻) was demonstrated. The uptake and elution reactions are analogues to that shown in eqn [2]. As with NiHCF, PVF can also be used as conventional IX materials. Specifically, the NO₃⁻ in (PVF⁺)(NO₃⁻) is readily exchanged for ReO₄⁻. Other possible applications for PVF include the extraction of arsenates and chromates.

PVF has been prepared through chemical, electrochemical, and plasma polymerization. Both plasma

and electrochemical polymerizations should be suitable for depositing PVF within porous substrate.

Applications The preference of polyvinylferrocene for perrhenate (nonradioactive chemical analogue of pertechnetate) anions over nitrate anions has been demonstrated. Nitrates are the main competing anions for separation of pertechnetate in radioactive tank wastes. The current and the frequency responses of a PVF-coated EQCM as a function of a cyclic potential scan are shown in Figure 11(A) and (B). (The frequency response is shown rather than the normalized mass change because of complications due to the less rigid PVF films compared to the NiHCF films.) The more negative (cathodic) potential peaks observed in the pure ReO₄⁻ solution and in the mixture, compared to a pure NO₃⁻ solution, indicate the preference of ReO₄⁻ over NO₃⁻. In addition, the frequency responses shown in Figure 11(B) indicate a substantial mass gained in the PVF film upon oxidation in a solution containing both NO₃⁻ and ReO₄⁻, more mass than can be attributed to NO₃⁻ alone. This supports the contention that ReO₄⁻ ions (which are heavier than NO₃⁻) are preferentially taken up by the PVF. The data shown in Figure 11(A) and (B) correspond to a separation factor of 30.

Future Developments

EIX processes (using EaIX and nonelectroactive IX materials) are very promising methods for ion separation due to the potential savings resulting from minimization of secondary waste generation. Better understanding of system performance through large-scale (e.g., pilot-scale) studies still needs to be carried out as well as the development of new materials. For example, EaIX materials selective for strontium (Sr²⁺) are of interest to the nuclear industry. Calcium (Ca²⁺) selective materials are valuable for preventing scale formation in many industries. Finally, effective removal of NO₃⁻ and arsenate anions is critical for safe drinking water.

Introduction

Separations with synthetic membranes have become increasingly important; today membrane processes are used in a wide range of applications and their number will certainly increase.

A membrane is a permselective polymer, inorganic or metal phase which restricts the motion of certain species. By controlling the relative rates of transport of various species it gives one product depleted in certain components and a second product concentrated in these components. Membrane performance is characterized by two terms: flux and selectivity. Flux (or permeation rate) is the volumetric mass flow of fluid passing through the membrane per unit area of membrane and unit mass time. Selectivity is a measure of the relative permeation rates of different components through the membrane.

Processes may be classified according to the driving force used: (1) a pressure differential leads to micro-, ultra- and nanofiltration and reverse osmosis; (2) a concentration difference across the membrane leads to diffusion of a species between two solutions (dialysis); (3) a potential field applied to an ion exchange membrane leads to migration of ions through the membrane (electrodialysis, membrane electrolysis and electrochemical devices). This last category and more specifically electrodialysis is the subject of this section. This electrically driven process uses ion exchange membranes, a description of which follows.

Ion Exchange Membranes

Electrodialysis (ED) uses membranes containing fixed charged groups attached to the polymer backbone of its membrane. Two kinds of ion exchange membranes (IEMs) are used in ED: *homopolar membranes*

bearing fixed charges of the same sign and *bipolar membranes* bearing positive and negative fixed charges located on each side of the membrane.

IEMs are sheet-shaped materials through which a selective ion transport can be established under a driving force, generally an electric field and/or a concentration gradient.

Most of them are of a polymeric nature. They are constituted of reticulated macromolecular chains forming a tridimensional structure. In this network, ionizable functionalized groups are attached to the polymeric matrix and are at the origin of the membrane selectivity. For example cation exchange membranes (CEMs) contain fixed negative charges and mobile cations which can be exchanged with other cations present in an external phase in contact with the membrane. The ions balancing the fixed exchange sites are called counterions. The concentration of counterions is relatively high and therefore counterions carry most of the electric current through the membrane. The fixed charges attached to the polymer matrix repel ions of the same charges (co-ions). This exclusion, which is a result of electrostatic repulsion, is called Donnan exclusion, named after F. G. Donnan, who first reported the phenomenon in 1910. However, as the membrane selectivity is never ideal, the membrane material can be penetrated by a non-negligible amount of electrolyte. A schematic structure of such a homopolar CEM is depicted in Figure 1. Under an applied electric field, the CEM bearing sulfonic exchange groups ($-\text{SO}_3^-$) mainly allows the transport of counterions.

A bipolar membrane (BPM) is composed of two layers of ion exchangers joined by a hydrophilic junction. The diffusion of water from both sides of the BPM allows it to dissociate under the electrical field to generate protons and hydroxyl ions, which further migrate from the junction layer through the cation exchange and anion exchange layers of the bipolar membrane. Generally, the cation exchange groups are sulfonic and the anions are trimethyl quaternary

Figure 1 Schematic process of transport of counterion (Na^+) through a cation exchange membrane (CEM, bearing sulfonic sites).

ammonium groups ($-\text{N}(\text{CH}_3)_3^+$). The principle of this water-splitting phenomenon is depicted in **Figure 2**.

The requirements for suitability of homopolar IEMs for industrial applications are the following:

1. high ionic conductivity with a concentration of fixed charges as high as possible;
2. high ionic permselectivity combining simultaneously a high conductivity and a moderate water uptake;
3. chemical stability of the fixed ions and a good mechanical resistance;
4. reasonable price.

Bipolar membranes must have all of these requirements and, in addition, must have an experimental potential to achieve a water-splitting capability as close as possible to the theoretical one, equal to 0.83 V at 25°C.

Nowadays, superior styrene-divinylbenzene copolymer membranes can be easily purchased; perfluorinated membranes with great chemical stability

are now being marketed and BPMs with an industrial-scale lifetime are becoming available.

Principles of Electrodialysis

Electrodialysis with Homopolar Ion Exchange Membranes

IEMs can be organized into two-, three- or four-compartment electrodialysis cells.

Two compartment electrodialysis The principle of ED is depicted in **Figure 3**. Electrically charged membranes are used to remove ions from an aqueous solution. A number of anion exchange membranes (AEMs) and CEMs are placed in an alternative pattern between a cathode and an anode. When an ionic feed solution (for example, a sodium chloride solution) flows through the channels of the electrodialyser, the positively charged sodium ions migrate to the cathode and the negatively charged chloride ions migrate to the anode. As the chloride ions

Figure 2 Schematic principle of water dissociation by a bipolar membrane (BPM).

Figure 3 Schematic of two-compartment electrodialysis. AEM and CEM, anion and cation exchange membranes; (D), dilute; (C), concentrate.

cannot pass the CEM and the sodium ions cannot pass the AEM, the overall effect is a simultaneous ionic concentration increase in alternating compartments and an ionic concentration decrease in the other compartments. Consequently, alternate dilute and concentrated solutions are formed. A set of two compartments (dilute (D) and concentrated (C)) forms a cell pair. In commercial applications several hundreds of cell pairs are assembled in a stack.

Three compartment electrodialysis A three-compartment ED process is depicted in Figure 4 and concerns the transformation of an electrolyte M^+X^- into its acid HX , which is weakly dissociated, according to the reaction:

The strong acid H^+A^- (HCl or H_2SO_4) is introduced into the feed compartment (F). Protons migrate to the substitution compartment (S) to transform the salt $(M^+X^-)_S$ into the weak acid $(HX)_S$. Simultaneously,

Figure 4 Schematic of three-compartment electrodialysis for the conversion of a salt M^+X^- into its weak acid HX .

Figure 5 Schematic of four-compartment electrodialysis for the double substitution reaction.

M^+ ions migrate to the recovery compartment (R) to form the salt $(M^+A^-)_R$.

Four-compartment electrodialysis A complex four-compartment ED process is depicted in Figure 5. The elementary cell is composed of four compartments and allows the reaction of double substitution according to

The electrolytes to be substituted, (B^+A^-) and (C^+D^-) , feed the dilutes D1 and D2. In the first recovery compartment R1, A^- combines with C^+ to give C^+A^- , while simultaneously B^+ combines with D^- to give B^+D^- in the second recovery compartment.

Process parameters and limiting phenomena in electrodialysis The amount of ions transported through the membrane is directly proportional to the electric current (i) or current density, which is given by

$$i = \frac{ZFQ\Delta c}{\eta}$$

where z is the valency, F the Faraday constant, Q the flow rate, Δc the concentration difference between the feed and the permeate (dilute) and η the current efficiency. Theoretically, 1 faraday of current (96 500 coulombs) will transfer 1 mol of sodium ions to the cathode and 1 mol of chloride ions to the anode. Practically, the permeation of water through the ion exchange membranes and the fact that the membranes are not completely selective slightly reduces the current efficiency to an average of 0.90–0.95.

Electric current is related to electrical potential E by Ohm's law:

$$E = Ri$$

where R is the resistance of the total membrane stack. Increasing the current density leads to an increase in the number of ions transferred. However, current density cannot be increased by an unlimited amount. In the steady state, the flux of a species through a membrane can never exceed the flux of that species to the surface of the membrane. Concentration polarization is a well-known phenomenon arising at the interface between an IEM and an electrolyte solution when current passes through it. It is due to the difference in transport numbers of the counterion between the membrane and the solution. Gradients of concentration arise in the diffusion layer as depicted in **Figure 6**, and when the concentration of the counterions becomes negligible at the depleted solution-membrane interface a limiting current appears.

This limiting current density j_L is the current density when the flux of ions through the boundary layers has reached its maximum value and no further increase in ion flux (or current) is possible. It is given by the relation.

$$j_L = \frac{zDFC}{\delta(t_m - t_s)}$$

where D is the diffusion coefficient of the counterion in the solution, C the concentration of the bulk solution, δ the thickness of the diffusion layer (also named the Nernst layer or unstirred boundary layer), and t_m and t_s are the transport number in the membrane and the solution, respectively. If the current density is allowed to exceed j_L , then the current crossing the membrane must be carried by another ion and dissociation of water occurs at higher current density. The limitations of the rate of ion transport through a membrane can be seen from a current density versus voltage plot for the membrane as depicted in **Figure 7**. This current-voltage plot is composed of three regions: a first, ohmic one in which current is carried

Figure 6 Concentration profile in diffusion layers: depleted and concentrated regions (for a cation exchange membrane).

Figure 7 Current-voltage curve for an ion exchange membrane; limiting current.

by the ions of the electrolyte, a second plateau-shaped one corresponding to the limiting current, and a third region in which water splitting occurs. Because D/δ is equal to k , the mass transfer coefficient, j_L is strongly determined by the hydrodynamics of the system (cross-flow velocity, geometry of the cell). Moreover, the distance between membranes has to be very thin to reduce the ohmic drop due to the electrolyte thickness. Practically, separators of 0.8–1.5 mm thick acting as turbulent promoters are introduced alternately into membranes.

Electrodialysis with Bipolar Membranes

The conventional method for generating H^+ and OH^- ions from water utilizes electrolysis. Electrolysis also generates O_2 and H_2 , and the overvoltage for this generation consumes about half of the electrical energy of the process. Nowadays, special ion exchange membranes are available for splitting water directly into H^+ and OH^- ions without generating gases. Membrane water-splitting technology is a general-purpose unit operation for converting water-soluble salts to their corresponding acids and bases. The process uses BPMs in conjunction with conventional CEMs and/or AEMs, respectively). The separation and rearrangement of ions is effected by a direct current driving force. BPM electrodialysis (EDBM) is therefore an alternative method of electrolysis for the generation of H^+ and OH^- ions which can be used to generate acid and base from salts, without the production of oxygen and hydrogen gases.

The principle of water splitting by a BPM is illustrated in **Figure 8**. The diffusion of water from both sides of the BPM allows its dissociation under the electrical field to generate protons and hydroxyl ions, which further migrate from the junction layer through the cation exchange and anion exchange layers of the BPM.

Figure 8 Diffusion and dissociation of water in a bipolar membrane. AEL and CEL, anion and cation exchange layers.

The application of BPM reduces the energy costs associated with electrode polarization in the more conventional electrolytic approach.

The theoretical potential to achieve the water-splitting capability is 0.83 V at 25°C. The actual potential drop across a BPM is quite close to this, being in the range of 0.9–1.1 V for current densities between 500 and 1500 A m⁻², which is the general region of practical interest. The value of the membrane potential drops equate to theoretical energy consumptions of the order of 600–700 kWh per ton of NaOH. Of course, the actual energy consumptions are significantly higher because of the ohmic resistances in the other cell stack components, in practical operating units.

The configuration of the EDBM process depends on the application. Typical use of BPM is in the treatment of concentrated salt solutions such as Na₂SO₄ from the chemical industry to produce H₂SO₄ and NaOH. A cell system consists of an AEM, a BPM and a CEM as a repeating unit. In this case the configuration is a *three-compartment EDBM*, illustrated in **Figure 9**. This elementary cell is repeated

Figure 9 Generation of H₂SO₄ and NaOH from Na₂SO₄ solution (three-compartment cell).

and placed between two electrodes. The Na₂SO₄ solution flows between the CEM and the AEM. When direct current is applied, water will dissociate in the BPM to form the equivalent amounts of H⁺ and OH⁻ ions. The H⁺ ions permeate through the cation exchange side of the BPM and form H₂SO₄ with the sulfate ions provided by the Na₂SO₄ solution from the adjacent cell. The OH⁻ ions permeate the anion exchange side of the BPM and form NaOH with the sodium ions permeating into the cell from the Na₂SO₄ solution through the adjacent CEM. The final result is the production of NaOH and H₂SO₄ from Na₂SO₄ at a significantly lower cost than by other methods.

There are applications where it is not possible to obtain high purity of both acid and base, or may even generate problems during the process. For example, in the splitting of a salt from a weak acid (sodium acetate), the pure acid is weakly dissociated, so its conductivity is low. It would not therefore be practical to achieve the splitting of sodium acetate in a three-compartment cell. Instead, a two-compartment cell with the acetate solution flowing between a BPM and a CEM is recommended (**Figure 10A**). When the conversion of the salt stream reaches 95%, the conductivity becomes very low. Therefore it is not possible to pursue the EDBM more deeply. The EDBM is then stopped and the residual Na⁺ ions are removed using cation exchange resins. In a similar way, an ammonium or amine salt can be treated in a two-compartment cell with an AEM instead of a CEM (**Figure 10B**).

BPM can thus also be used in an alternative two-compartment cell configuration, regenerating only one base or acid. The cation/BPM two-compartment cell is useful for the processing of the salts of weak acids (or organic acids) to give a relatively pure base stream and a mixed acid/salt stream (**Figure 10A**), while the anion/BPM configuration is useful for converting salts of weak bases (e.g. ammonium nitrate) to a salt/base mixture and a relatively pure acid (**Figure 10B**).

Applications of Electrodialysis

Electrodialysis with Homopolar Membranes

Separation electromembrane processes such as ED are being applied to bioindustries and to the treatment of industry of wastewater. ED is a method which is used both for the removal of salts (e.g. to produce drinking water from brackish sources, to remove salts from foodstuffs) and for the concentration of salt solutions (e.g. for the manufacture of table salt from seawater, the concentration of process

Figure 10 Two-compartment bipolar membrane electrodialysis to produce only pure acid or base.

streams and the recovery of salts from effluents). An example of conventional two-compartment ED is depicted in **Figure 11** and some of the many applications of ED are listed in **Table 1**.

The main application of ED is the production of potable water from brackish water whose salt content is close to 5 g L^{-1} . Beyond this value the reverse osmosis technique is more suitable. A new application of desalination is the reduction of nitrate content in drinking water. AEMs tend to selectively transfer nitrate in preference to other anions common in drinking water. Nowadays, electrodialysis plants produce several hundreds of cubic metres of potable water per day (reduction of nitrates to 5 mg L^{-1} and NaCl to 200 mg L^{-1}).

Another potential increasing area for ED is in the rough desalting of water that will be subjected to subsequent purification for use as boiler feed or rinse water in the electronics industry. Ion exchange has commonly been used for preparing waters with a very low salinity. However, the cost for regenerating and the magnitude of the waste disposal problem are proportional to the salinity of the feed water. A variant of ED which has achieved commercial success is electrodeionization. The depleted compartment is filled with an ion exchange material, generally an ion exchange resin. This material, providing high conductive paths for the ions, prevents the occurrence of the concentration polarization and a drastic increase of the electrical resistance. **Figure 12** illustrates the electrodeionization process with ion exchange resins. It allows the production of high resistivity water ($10\text{--}15 \text{ M}\Omega \text{ cm}^{-1}$) from water treated by reverse osmosis ($50\text{--}100 \text{ k}\Omega \text{ cm}^{-1}$). Ion exchange resins can be replaced by ion exchange textiles, which present a higher porosity and allow operation at high flow rates. Moreover, due to their sheet form, ion exchange textiles maintain their shape and dismantling of ED stacks for clearing or repair is easier.

The second historical application of ED is the concentration of recovered salts to high levels. That capa-

Table 1 Applications of electrodialysis with homopolar membranes

<i>Reduction of electrolyte content</i>	<i>Recovery of electrolytes</i>
Potable from brackish water	Pure NaCl from seawater
Food products, milk whey, fruit juice	Ag(I) salts from photographic waste
Nitrate from drinking water	Ni(II) from electroplating rinse water
Rinse water for electronics	Zn(II) from galvanizing rinse water
Effluent streams	Salts of organic acids from fermentation broths
Electroless plating baths	Acids from metal pickling baths and rinse
Protein hydrolysates	Amino acids from protein hydrolysates
Sugar and molasses	HCl from cellulose
Potassium tartrate from wine	
Chloride purge in kraft paper process	<i>Miscellaneous</i>
Photographic developer regeneration	Ion substitution

bility has been used for the recovery of crystalline NaCl from seawater. There are several ED plants in Japan with 100 000 m² of ED membranes being used for NaCl recovery from seawater. Another important field of ED application has been in whey desalting. Whey is a by-product from cheese making containing useful quantities of proteins, lactose and lactic acid. However, the high mineral content makes it unacceptable for human consumption and of marginal value for animal feed. In terms of membrane area installed, this application is the third largest ED process. ED also has important applications in the pharmaceutical and biochemical industries, where gentle processing conditions are required for materials such as human blood plasma. The production of essential amino acids will require various demineralization steps. Certain waste streams in biochemical and pharmaceutical operations contain ammonium sulfate, urea and guanidine hydrochloride which can be recovered by ED. There are several other applications of ED for salt removal which include the production of protein fractions and the separation of amino acids into acidic, basic and neutral groups. Concerning this

latter example, amino acids are mainly produced from protein hydrolysates. The solutions obtained contain both natural amino acids and inorganic salts and therefore necessitate a demineralization step. **Figure 13** shows the two-compartment ED configuration for this operation. The hydrolysates to be treated are generally mixtures containing 2–3 mol L⁻¹ of amino acids and 2.5 M NaCl at pH 5–6.

The diluate containing hydrolysate is demineralized from 2.5 M to 0.2 M without significant loss of amino acids. Such a process is running on an industrial scale in Europe. The second step is the obtention of fractions of amino acids. This operation is achieved by a four-compartment ED as depicted in **Figure 14**. Charged amino acid forms are less mobile than the ions of the salts. During this operation pure anionic and cationic amino acid fractions are obtained in the concentrate compartments (C1 and C2, respectively), while the zwitterionic forms remain in the diluate D1. The zwitterionic fraction will then be purified using a BPM.

ED is also applied to the treatment of inorganic media. The metal-finishing industry offers numerous

**Figure 12** Schematic of the electrodeionization process. The ion exchange material (resin or textile) fills the diluate compartment.

Figure 13 Schematic of the demineralization of protein hydrolysates by electrodialysis. (Reproduced from Sandeaux *et al.*, 1998, with permission from John Wiley & Sons Limited.)

applications for ED in pollution control and material recovery. The rinse streams from such processes pose pollution problems. They are usually too dilute for direct metal recovery and too concentrated for disposal. For example, ED processing of a rinse stream from a nickel electroplating system allows the production of a dilute stream to be recycled in the rinse tank and a concentrated stream which can be recirculated in the electrodialysis to build up its metal content to a level that is useful for further recovery or direct return to the plating bath. Other similar applications concern the removal of phosphite from an electroless nickel bath or the recovery of HF and HNO₃ used to clean stainless steel.

Industrial countries are increasingly concerned with environment protection issues. The treatment of spent acids containing divalent metallic salts is a problem in several industries where these acids are used in pickling and surface treatment of metals. ED is an attractive technique for treating these waste acids because purified and reconcentrated acids can be obtained and reused. The advantage of this process

is not only the possibility of recycling acids but also the production of lower amounts of salt effluents or sludges. For example, the recovery of sulfuric acid from effluents containing metallic salts (Mg, Zn, Mn, 50 g L⁻¹) in an H₂SO₄ solution (200 g L⁻¹) from zinc hydrometallurgy is achieved in a two-compartment ED cell with modified CEMs having high selectivity protons/multivalent cations, and AEMs having a low proton leakage (Figure 15). A solution of 150 g L⁻¹ H₂SO₄ containing less than 0.5 g L⁻¹ of metals was so obtained.

Electrodialysis with Bipolar Membranes

A large number of applications have been identified. The applications have been classified under the broad categories of pollution control/resource recovery and chemical processing in Table 2.

The oldest industrial application of EDBM in pollution/control resource recovery is the recovery of HF and HNO₃ from a stream containing KF and KNO₃ generated from pickling baths in the steel plant.

Figure 14 Schematic of four-compartment electrodialysis for obtaining anionic forms (in C1), cationic forms (in C2), and zwitterionic amino acids (remaining in D1). (Reproduced from Sandeaux *et al.*, 1998, with permission from John Wiley & Sons Limited.)

Figure 15 Schematic of the recovery of an acid by electrodialysis. Diluate: H_2SO_4 and MSO_4 . Pure H_2SO_4 is obtained in the concentrate.

This first commercial use of BPM began operation in 1987 at Washington Steel in Pennsylvania. **Figure 16** illustrates the process. Spent pickling acid is neutralized with KOH to precipitate the heavy metals, which are then removed by filtration. The remaining neutral solution of $\text{KF} + \text{KNO}_3$ is then treated in a three-compartment EDBM cell in which the salts are split to form KOH, which is directed to the neutralization tank, and the mixed acids ($\text{HF} + \text{HNO}_3$),

which are directed to the pickling operation. The dilute salt solution from the salt compartment of the EDBM process is then reconcentrated by conventional ED and is then returned to the bipolar stack, while the diluate is used to rinse the filter cake.

The main application of EDBM in chemical processing is the recovery of organic acids which can be recovered from fermentation. The performance of fermentation is better when the pH is slightly higher

Table 2 Some technology applications of water splitting on BPM

<i>Pollution control/resource recovery</i>	
HF/mixed acid recovery	Stainless steel pickle liquor recovery HF/NaOH recovery from spent aluminium potlinings Fluorosilicic acid conversion to HF, SiO_2 Fluoride emission control in chemical processing
Sulfate recovery	Battery acid recovery Waste sodium sulfate conversion Sodium sulfate conversion in rayon manufacture
Nitrate recovery	Ammonium nitrate conversion from uranium processing KNO_3 conversion Recovery of catalyst used to cure epoxy resins in Al coating moulds
Amine recovery	Sodium alkali recycling in pulping and bleaching operations
Pulp and papers	Soxal® process SO_2 recovery
Flue gas desulfurization	Dry sodium scrubbing alkali recovery
<i>Chemical processing</i>	
Organic acid production recovery	Acetic, formic, acetylsalicylic and organic acids Amino acids
Ion exchanger regeneration	Production of highly generated ion exchange resins
Potassium and sodium mineral processing	KCl conversion Solution mining of trona and subsequent sodium alkali production
Sodium methoxide production	Sodium alkali production from natural brines and solid trona
Methanesulfonic acid production	EDBM in methanolic solutions
High purity water production	EDBM of sodium methanesulfonate Continuous electrodeionization
